Abstract:	<p>A new droplets millifluidic/inverse gelation based process was used to produce core-shell alginate milli-capsules. Water-in-oil (W/O) emulsion dispersed phase containing Ca²⁺ ions was directly injected into a continuous alginate phase to generate a secondary W/O/W emulsion. Due to the cross-linking of alginate molecules by Ca²⁺ ions release, core-shell milli-capsules were formed with a very high oil loading. The influence of the curing time and of the storage conditions on capsules physico-chemical properties was investigated.</p> <p>It was first found as expected that alginate membrane thickness increased with curing time in the collecting bath. However, a plateau was reached for the higher curing times, in close relation with previous observations (Martins, Poncelet, Marquis, Davy, & Renard, 2017b) that an external oil layer surrounded the surface of W/O emulsion drops that acted as a barrier and hindered the release of aqueous CaCl₂ droplets during curing time. Compression experiments on individual capsules revealed that alginate membrane thickness was inversely related to its mechanical properties, i.e. the thicker membrane, the lower surface Young modulus. Surface Young modulus ranged from 61 to 26 N/m at curing times of 3 and 45 min, respectively. This result was explained in terms of enhanced swelling properties of alginate membrane with curing time or storage conditions. Drying capsules led to much more resistant membranes due to the loss of water. Oil loading of 80 wt% was obtained for dry capsules whatever the conditions used.</p>	

Response to Reviewer 3 Comments

Point-by-point answers to reviewer 3 are given below and corrections appear in red in the revised manuscript.

Reviewer #3: I have reviewed this manuscript titled „CHARACTERIZATION OF CORE-SHELL ALGINATE CAPSULES GENERATED USING DROPLETS MILLIFLUIDIC" based on the innovativeness, quality, significance, and presentation of results. In general, the presentation of results is lacking. This paper could be published but only after the corrections and explanations.

Line 29. Change „was" to „were".

Changing was made in the revised manuscript.

Line 63. Change „consist" to consists".

« Consists » appears in the original manuscript.

Line 85. Change „the microcapsules production" to „the production of the microcapsules".

Changing was made in the revised manuscript.

Line 126. Change „were" to „was".

Changing was made in the revised manuscript.

Line 150. Were capsules washed before storage in Ca²⁺ or Na⁺ containing solutions?

According to reviewer's remark, the following sentence was changed in the revised manuscript "the capsules were sieved, rinsed with distilled water and suspended in a Ca²⁺ or Na⁺ solution".

Line 165. Change „microscopy" to „microscope".

Changing was made in the revised manuscript.

Line 224. Change „hydrophilic lipophilic" to „hydrophilic-lipophilic".

Changing was made in the revised manuscript.

Line 236. High-pressure homogenization? Where is this included in the paper? There is no mentioning of High-pressure homogenization throughout the paper.

We agree with reviewer 3 and the following changing was made in the revised manuscript « High shear mixing... »

Figure 5 and Figure 7. Are there statistically significant differences with regards to the curing time and membrane thickness/capsule diameter? Are there statistically significant differences with gelation time? These should be added to the figures and comment in the discussion.

Authors performed statistical analyses on data displayed in Figures 5 and 7. The following sentence was therefore added in the Figure captions of the revised manuscript : «At the 0.05 level, the populations means were significantly different ». In addition, authors added in the caption of Figure 5 « Solid line corresponded to the fitting of the data by a linear function; dotted line was just eye-guide. » Authors also replaced « Gelation time » by « Curing time » in Figure 7. Finally, additional comments regarding statistical analyses were added in the revised manuscript.

Table 2 and Figure 9 seem to have a repetition of the data for membrane thickness. Also are there significant differences found between 3h, 24h, and 48h in Figure 9?

The repetition of the data between Table 2 and Figure 9 is only true for data obtained after 48h storage of capsules. Figure 9 therefore also displayed evolution of membrane thickness in time after 3, 24 and 48h storage of capsules.

Authors performed statistical analyses on data displayed in Figure 9. The following sentence was therefore added in the Figure caption of the revised manuscript : «At the 0.05 level, the populations means were significantly different ».

Regarding the writing, some corrections should be applied to add/remove articles the/a/an.

Changes were made according to reviewer 3 where articles « the/a/an » were in strikethrough text in the revised manuscript (or sometimes added in the revised manuscript).

Response to Reviewer 4 Comments

Point-by-point answers to reviewer 4 are given below and corrections appear in red in the revised manuscript.

General comments

The objects of the paper are interesting and it makes sense to investigate the droplet characteristics of capsules formed by inverse gelation in more detail. However as Ca-alginate gels are highly porous gels, I seriously doubt about the protective effect of a Ca-Alginate layer against oxygen and water. What is the mean pore size of this protective layer? How can the gel protect against the diffusion of water?

Authors have no doubt about the porosity of alginate beads for which values ranging from 5 to 200 nm were obtained using TEM (Andresen et al. ACS Symp. Ser. 1977; 48 361-381) while values ranging from 12 to 16 nm were obtained using size exclusion chromatography (Klein et al. Eur. J. Appl. Microbiol. Biotechnol. 1983 18 86-91). The differences in porosity were explained by a difference in porosity between outside (pores of small size) and inside (pores of large size) of alginate beads (Smidsrod, Carb. Res. 1973 27 107-118). Authors suppose that the differences in porosity identified by Smidsrod could also exist in alginate membrane of capsules. The wide distribution of pores size therefore gives alginate beads and capsules a wide range of applications and in particular in drug delivery applications.

Specific comments

p. 4 line 76: the solution could also be sprayed instead of dripped to get smaller capsules

Authors totally agree with reviewer 4. The following sentence was therefore added in the revised manuscript: "Alternative to reduce size is therefore to spray alginate solution rather than dripping to a bath of CaCl₂ solution [7]."

The objective of the work is not made clear.

According to reviewer 4, authors have modified lines 105 to 109 to make objective of the work clearer.

The objective of the present work is, therefore, to produce core-shell alginate milli-capsules using a new droplets millifluidic/inverse gelation based process. The contribution tends to analyze the effect of varying curing time and cation concentration of the storage solution on the final properties of the obtained capsules, including oil content and mechanical properties.

p. 5 line 107 To study the effect of cation concentration is not mentioned at all in the introduction part and it seems that this study was added to explain the change in young modulus with shell thickness

The effect of cation concentration is mentioned page 5 line 107 "...varying the curing time and the cation concentration of the storage solution...".

2.1 line 117 ff: why is tween 20 not mentioned?

Tween 20 (Sigma Aldrich, France) was therefore added in the material section line 122 in the revised manuscript.

2.3.3 line 179: Is alginate solution Newtonian?

Authors have determined that low concentration solution of alginate at C = 1% and sunflower oil were both Newtonian while W/O emulsion displayed a shear-thinning behaviour (data not shown as authors thought that it did not bring useful information to understand the contribution).

Table 1: What is D

D corresponds to the capsule diameter. Table 1 was therefore corrected as follows in the revised manuscript:

	Diameter D (mm)	Membrane thickness m (μm)	D/m	Surface Young modulus (N/m)	Force at break (N)
Wet capsules	2.21 \pm 0.07	297 \pm 76	7.4 \pm 0.3	26.1 \pm 1.8	1.15 \pm 0.27
Dry capsules	1.85 \pm 0.14	27 \pm 12*	60.1 \pm 5.9	613 \pm 163	1.45 \pm 0.37

Fig. 3 curves are difficult to distinguish

Authors agree with reviewer 4 and Figure 3 was redrawn in the revised manuscript by plotting data with different colours.
p. 12 285: How was the oil content of the dried capsules quantified?

Oil content was determined by TGA for both wet and dried capsules. The sentence in the revised manuscript was rephrased as follows: "By this way, it was therefore possible to use this technique to determine the oil content of the wet and dried capsules between 300 and 510°C".

Fig.4: Why did you choose different regions of interest and different magnifications?

Micrographs were taken at different regions of interest in order to highlight membrane growth and heterogeneity as function of curing time. Scale bar was constant at 250 μ m for all micrographs.

Fig. 5: How is polydispersity defined and where do I find this value in the plot? I don't see an exponential increase as indicated in the text but a linear increase and saturation above a certain curing time

Authors totally agree with remark of reviewer 4 as polydispersity was not properly defined in the manuscript. Size polydispersity resulted from size measurements of capsule diameters using microscopy and could be ascribed to the standard deviation divided by the average size. The following sentence was therefore added in the revised manuscript: "The average diameter of alginate capsules ranged from 1.9 to 2.6 mm depending on curing time (significant differences at $p < 0.05$), with a size polydispersity lower than 10% (i.e. standard deviation / average size)".

Regarding the evolution of membrane thickness versus curing time, authors totally agree with the remark of reviewer 4. Authors therefore rephrased the sentence s follows in the revised manuscript: "From Figures 4 and 5, it was concluded that capsule diameter and membrane thickness were linearly dependent on curing time; in addition, membrane thickness reached a plateau at high curing times due to restricted calcium diffusion."

Table 2: Units are missing

Authors corrected Table 2 in the revised manuscript as follows:

Storage solution (wt%)	Diameter (d, mm)	Membrane thickness (Mt, μm)	d/Mt	Surface Young modulus (Es, N/m)	Es/Mt (N/m/μm)
Distilled Water	2.27 \pm 0.20 ^{a,c}	479 \pm 74 ^a	4.7 \pm 0.3 ^{a,d}	23.4 \pm 2.64 ^a	0.049
CaCl ₂ 0.1	2.43 \pm 0.17 ^{a,b,c}	388 \pm 84 ^{a,b,c}	6.3 \pm 1.7 ^{a,b,c}	28.7 \pm 4.6 ^a	0.073
CaCl ₂ 0.3	2.33 \pm 0.18 ^{a,b,c}	316 \pm 44 ^{b,c}	7.4 \pm 1.4 ^{b,c}	39.5 \pm 3.3 ^{b,c}	0.125
CaCl ₂ 1	2.40 \pm 0.19 ^{a,b,c}	392 \pm 61 ^{a,b,c}	6.1 \pm 1.1 ^{a,b,c}	29.1 \pm 6.6 ^{a,b}	0.074
CaCl ₂ 1.5	2.60 \pm 0.14 ^b	345 \pm 48 ^c	7.5 \pm 1.1 ^c	42.6 \pm 6.9 ^c	0.123
NaCl 1.5	2.11 \pm 0.14 ^c	748 \pm 96 ^d	2.8 \pm 0.5 ^d	2.3 \pm 0.1 ^d	0.003

Fig. 8a: I can't see a linear decrease and the linear regression line is not justified at all!

Authors agree with remark of reviewer 4 where linear fitting of data in Figure 8a was highly speculative. The following figure was included in the revised manuscript where a discontinuous line was added as an eye-guide:

Fig. 8b and 8c: No plateau can be found as indicated in the text

Authors agree with remark of reviewer 4. This mistake was therefore corrected in the revised manuscript as follows: “This phenomenon was clearly seen on Figures 8b and 8c where a linear decrease was noticed for the surface Young modulus with the increase of membrane thickness and diameter / thickness ratio.”

p. 18 line 419: How does the young modulus change with curing time for dried microcapsules?

Measurements of the Young modulus were performed on dried capsule only at constant curing time (30 min).

23 **ABSTRACT**

1
2 24 A new droplets millifluidic/inverse gelation based process was used to produce core-shell
3
4 25 alginate milli-capsules. Water-in-oil (W/O) emulsion dispersed phase containing Ca^{2+} ions
5
6
7 26 was directly injected into a continuous alginate phase to generate a secondary W/O/W
8
9
10 27 emulsion. Due to the cross-linking of alginate molecules by Ca^{2+} ions release, core-shell milli-
11
12 28 capsules were formed with a very high oil loading. The influence of the curing time and of the
13
14 29 storage conditions on capsules physico-chemical properties were investigated.

16
17 30 It was first found as expected that alginate membrane thickness increased with curing time in
18
19 31 the collecting bath. However, a plateau was reached for the higher curing times, in close
20
21 32 relation with previous observations (Martins, Poncelet, Marquis, Davy, & Renard, 2017b) that
22
23 33 an external oil layer surrounded the surface of W/O emulsion drops that acted as a barrier and
24
25 34 hindered the release of aqueous CaCl_2 droplets during curing time. Compression experiments
26
27 35 on individual capsules revealed that alginate membrane thickness was inversely related to its
28
29 36 mechanical properties, i.e. the thicker membrane, the lower surface Young modulus. Surface
30
31 37 Young modulus ranged from 61 to 26 N/m at curing times of 3 and 45 min, respectively. This
32
33 38 result was explained in terms of enhanced swelling properties of alginate membrane with
34
35 39 curing time or storage conditions. Drying capsules led to much more resistant membranes due
36
37 40 to the loss of water. Oil loading of 80 wt% was obtained for dry capsules whatever the
38
39 41 conditions used.

48 **1. INTRODUCTION**

1
2 49 The study of microcapsules based on biodegradable polymers is of great importance in
3
4 50 current scientific research worldwide due to the unusual combination of properties and
5
6
7 51 versatility of these materials.

8
9 52 Microencapsulation avoids the degradation and volatilization of bioactives, protecting
10
11 53 and preserving their biological activity and active functional ingredients. The
12
13 54 microencapsulation technique has been mainly described as a process in which small particles
14
15
16 55 or droplets are surrounded by a homogeneous or heterogeneous coating, forming beads or
17
18
19 56 capsules with various applications [1]. There are three major fields of application: food
20
21 57 production, e.g. the enhancement of nutrition by encapsulated vitamins, minerals or even pro-
22
23 58 biotic bacteria; the cosmetic industry, where encapsulation of colors and flavors became more
24
25
26 59 and more popular within the last years; and the drug delivery field.

27
28
29 60 Oils are widely applied in the formulation of foods, pharmaceutical and cosmetic
30
31 61 products; however, they are often volatile, labile and sensitive to environmental factors such
32
33
34 62 as heat, light, water and oxygen [2]. An efficient strategy to decrease their sensitivity towards
35
36 63 environmental conditions consists of its encapsulation in inert polymer matrix using
37
38
39 64 gelation/emulsification technique [3-5].

40
41 65 Alginate is one of the most widely used biocompatible polymers in
42
43 66 microencapsulation, as it forms a highly versatile, biocompatible and nontoxic matrix of gel
44
45
46 67 that protects the active components of factors such as heat and moisture thereby enhancing
47
48 68 stability and bioavailability. Alginates are algal polysaccharides consisting of a linear chain of
49
50
51 69 (1-4) linked residues of β -D-mannuronic acid (M) and α -L-guluronic acid (G) in different
52
53
54 70 proportions and sequential arrangements [6]. This polymer has a remarkable property of quick
55
56 71 gelation in presence of divalent ions such as calcium ions (Ca^{2+}).

72 Among the different methods used to prepare beads of gelled alginate, the most widely
73 used encapsulation method is the simple extrusion/external gelation [7-8], wherein the
74 formation of beads containing the solution of alginate and the active to be encapsulated is
75 accomplished by using an extruder device dripping to a bath of CaCl₂ solution which induces
76 alginate gelation [1]. The main limitations of this technique are the large size of beads formed,
77 which depends on the diameter of the nozzle extruder, the large quantity of oil used to
78 generate emulsion drops which is generally wasted, and the difficulty of large scale
79 production because beads are formed one by one. **One alternative to reduce size is therefore to
80 spray alginate solution rather than dripping to a bath of CaCl₂ solution [7].**

81 On the other hand, in the inverse gelation mechanism, oil and CaCl₂ solution are
82 emulsified and added dropwise into an alginate solution bath [9], where Ca²⁺ ions diffuse
83 from the emulsion drop to the alginate bath cross-linking the surrounding alginate molecules
84 [9]. This technique allows producing core-shell capsules with an oil loading of nearly 100%
85 (v/v) for dry capsules by using the dispersion-inversion gelation technique [10]. In addition,
86 the **production of microcapsules** using droplets millifluidic is a promising strategy for oil
87 encapsulation and allows the easy production of highly controlled and uniform microcapsules
88 from W/O emulsions [11]. A similar droplets millifluidic set-up was used to produce core-
89 shell alginate capsules with an aqueous core instead of an oil core [12]. The millifluidic
90 device used in [11] consisted in a co-axial flow focusing geometry; water-in-oil (W/O)
91 emulsion drops containing Ca²⁺ are directly injected through a capillary or needle into the co-
92 flowing continuous phase (alginate solution) to form ~~the~~ micro-capsules downstream of the
93 circuit. The oil encapsulation using this gelation mechanism is a very recent approach and is
94 still scarcely studied [9, 2, 11]. For example, Martins et al. (2017b) studied the different
95 factors affecting ~~the~~ emulsion stability, ~~the~~ capsule size and ~~the~~ membrane thickness. This
96 study demonstrated the success of the production of (micro)-capsules based on the inverse

97 gelation mechanism using droplets millifluidic. Monodisperse (micro)-capsules with sizes
98 ranging from 1.4 mm down to 140 μm were produced. The present work can be considered as
99 a continuation of the work of Martins et al (2017b), where the focus was on the final
100 properties of capsules and more specifically on the mechanical properties and oil content of
101 the capsules. In many cases, the capsules are subjected to mechanical stresses exerted by their
102 environment that induce deformation and potential breakup. It is important to control the
103 mechanical properties of capsules to ensure protection and/or release of the encapsulated
104 substances under proper conditions and also to avoid breakup during processing. The present
105 study focused on capsules made of a deformable membrane with an internal liquid core.

106 The objective of the present work is, therefore, to take advantages of the new droplets
107 millifluidic/inverse gelation based process to produce core-shell alginate milli-capsules and to
108 analyze the effect of varying the curing time and the cation concentration of the storage
109 solution on the final properties of the obtained capsules, including oil content and mechanical
110 properties.

111 The use of millifluidic devices paves the way to an integrative formulation of core-
112 shell materials with a broad size range of monodisperse capsules (from μm to mm) and new
113 complex architectures. This should lead to the rapid emergence of new products in cosmetics
114 or food, where the texture and visual aspect play a key role for sale.

115 116 **2. MATERIALS AND METHODS**

117 ***2.1. Materials:***

118 Sodium alginate powder (Saltialgine S 60 NS) with a mannuronic (M) to guluronic (G) acid
119 unit ratio (M/G) and a molar mass equal to 1.37 and 1.57×10^5 g/mol, respectively, was
120 kindly donated by Cargill (France). Calcium chloride powder ($\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$) (Panreac
121 Quimica Sau, Spain), sunflower cooking oil (Associated Oil Packers, France), PGPR 90

122 (Danisco, France), Tween 20 (Sigma Aldrich, France) were used to prepare the W/O
123 emulsions. Other chemicals reagents were obtained from Sigma Aldrich (France).

124

125 **2.2. Methods:**

126 *2.2.1. Preparation of alginate and calcium chloride solutions*

127 Ten grams of alginate powder was dissolved in 1 L of demineralized water using a magnetic
128 stirrer. Tween 20 (0.5%, v/v) was added to the alginate solution. The calcium chloride
129 solution was prepared by dissolving 240 g of CaCl₂·2H₂O in 1 L of demineralized water.

130

131 *2.2.2. Preparation of the W/O emulsions*

132 Emulsions were prepared according to Martins et al. (2017b). One hundred millilitres of
133 sunflower oil containing 0.96 g of surfactant (PGPR 90) was mixed using a high shear mixer
134 (Ultra-Turrax T25, IKA, Germany) at 18 000 rpm for 1 min. Sixty millilitres of calcium
135 chloride solution (240 g/L) was then added slowly and a new shear mixing at 18 000 rpm for
136 3 min was performed.

137

138 *2.2.3. Capsules production by droplets millifluidic*

139 A millifluidic device with a co-axial flow focusing geometry was used as described in [11]
140 (Figure 1, Supplementary data). The dispersed phase, a W/O emulsion freshly prepared (see
141 section 2.2.2.) was pumped (Harvard Apparatus PHD 2000, France) through a fused silica
142 capillary tube (interior diameter (ID) 530 μm and outside diameter (OD) 660 μm) at a rate
143 (Q_{emul}) of 4 mL/h. The continuous phase, an alginate solution added with Tween 20, was
144 pumped through a Teflon tube (ID=1.57 mm and OD= 0.5 mm) at a rate (Q_{alg}) of 10 mL/h.
145 The W/O emulsion and the alginate solutions co-flowed in the glass tube (ID= 2 mm, OD= 4
146 mm and length of 10 cm). As the generation of capsules using W/O emulsion requires

147 hydrophilic surfaces, the glass tube was previously immersed in a saturated-NaOH solution
148 for 5 min at room temperature and rinsed using tap water [13].

149 W/O emulsion drops were formed and dispersed in the continuous alginate phase. Calcium
150 ions (Ca^{2+}) diffused from the W/O emulsion drop cross-linking the alginate molecules. The
151 capsules were collected in an alginate bath stirred at 50 rpm. After a curing time (time of
152 contact between the capsules and the alginate solution) varying between 3 and 50 min, the
153 capsules were sieved, **rinsed with distilled water**, suspended in a Ca^{2+} or Na^+ solution or in
154 distilled water and stored at 4°C until use.

155

156 ***2.3. Characterization of the W/O emulsions***

157 *2.3.1. Stability*

158 ~~the~~ W/O emulsion stabilities were performed as described by Martins et al. (2015). Hundred
159 millilitres of W/O emulsions were placed in tubes of 100mL with graduation of 1mL. The
160 emulsions were kept at ambient temperature ($20 \pm 2^\circ\text{C}$) and visually inspected as a function of
161 time in order to assess the critical time for which 1% of phase separation occurred (i.e.
162 corresponding to 1 mL of phase separated liquid).

163

164 *2.3.2. Microscopic observations*

165 W/O emulsions were diluted ten times in sunflower oil and observed under the microscope.
166 The diluted emulsions were brought on a **microscope** slide using a capillary after which a
167 cover slip was gently applied. Image acquisition was conducted using an optical microscope
168 (Leica Microsystems, France). The size of CaCl_2 solution droplets (dispersed phase) was
169 determined by image analysis using the ImageJ 1.47v freeware (National Institutes of Health,
170 Bethesda, Maryland, USA). ~~the~~ **M**Measurements were carried out in triplicate with three
171 repetitions. In other words, three W/O emulsions of each formulation were analyzed by

172 optical microscopy. Three different zones (1.1×1.5 mm) for each sample were imaged and
173 approximately one hundred droplets per zone were measured.

174

175 2.3.3. Rheological measurements

176 The viscosity of sunflower oil, alginate solution and water in-oil emulsions were investigated
177 with a stress-controlled rheometer (AR-2000, TA Instruments, New Castle, DE) equipped
178 with a Couette geometry (DIN 412). The temperature was controlled with a Peltier system.
179 ~~the~~ Dynamic viscosity and shear stress as a function of shear rate between 0.01 and 1000 s^{-1}
180 were measured. Viscosity of alginate solution at $C = 1\%$ (w/v) gave $\eta = 35.9 \pm 3.9 \text{ mPa.s}$
181 while that of sunflower oil was of $70.2 \pm 1.7 \text{ mPa.s}$. W/O emulsion had a viscosity $\eta = 212.5$
182 $\pm 7.4 \text{ mPa.s}$.

183

184 ***2.4. Characterization of capsules***

185 *2.4.1. Microscopic observation*

186 The External diameter (D), and membrane thickness (m) of capsules were performed under an
187 optical microscope (Olympus IX51, France) equipped with a camera (Olympus DP70). A 40X
188 objective was used to image microcapsules.

189 Dp controller software (version 2.1.1) was used for images acquisition. Shell thickness (M_t)
190 and capsules diameter (d) were therefore calculated from image analyses on 10 capsules per
191 experimental condition using the imageJ 1.47v freeware (National Institutes of Health,
192 Bethesda, Maryland, USA).

193

194 *2.4.2. Total oil content of the capsules*

195 A TGA Q5000 instrument was used for the thermo-gravimetric analysis (TGA). An
196 isothermal step at 60° C during 30 minutes was applied before the ramp up to 800° C at

197 10 °C/min under a nitrogen atmosphere (25 mL/min). The capsules were dried 48 h at room
198 temperature and $a_w=0.59$ (NaBr) before TGA analyses. Oil content was determined by
199 analyzing the thermograms of pure components and capsules.

201 *2.4.3. Mechanical study*

202 A Dynamic Mechanical Analyzer (Rheometric Scientific, EEUU) equipped with a plate-plate
203 geometry (diameter of 20 mm) was used. The upper plate had a diameter of 20 mm and the
204 normal force was measured as a function of the compression in a range between 0.001 and 20
205 N. A force gap test was used to compress the capsules with a linear compression speed of 0.6
206 mm / min. The gap and the normal force being imposed were measured simultaneously at the
207 upper plate. The surface Young modulus was calculated by a quantitative analysis of force–
208 displacement curves at small deformations [14-15]. Five replicates were considered for each
209 capsule.

211 *2.4.4 Statistical analysis*

212 Data values obtained in the experiments were statistically analyzed by one-way analysis of
213 variance (ANOVA) employing OriginLab 8.5 software. Differences between pairs of means
214 were assessed on the basis of confidence intervals using the Tukey test. The least significance
215 difference was $P < 0.05$.

218 **3. RESULTS AND DISCUSSION**

219 *3.1. Characterization of the W/O emulsions*

220 Emulsions containing sunflower oil, CaCl_2 solution (240 g/L) and PGPR 90 were prepared
221 using a high shear mixer. The dispersed W/O phase contained the calcium content that allows

222 to crosslink the alginate and form the membrane of the capsules. ~~the~~ Knowledge of the
1 stability is very important as it is directly related with the Ca²⁺ release, and therefore the
2
3
4
5 224 membrane formation.

6
7 225 PGPR 90 was chosen as emulsifier due to its low hydrophilic-lipophilic balance value
8
9
10 226 (HLB=1.5), which made it prone to stabilize W/O emulsions [16].

11
12 227 Several images of the emulsion in function of storage time, formed by dispersing calcium
13
14 228 aqueous phase into the sunflower oil containing the surfactant PGPR 90, were shown in
15
16
17 229 Fig. 1. Minimal phase separation and droplet coalescence occurred during storage over 24 h.
18
19 230 Martins et al (2017b) studied the effect of surfactant concentration on the stability of the
20
21
22 231 emulsions. By increasing emulsifier concentration, W/O emulsions with stabilities increasing
23
24 232 from 0.9 to 132 h were found. Marquez et al. [17] and Su et al. [18] found that higher the
25
26
27 233 emulsifier concentration was, lower was the size of water droplets in the W/O emulsion,
28
29 234 increasing both its viscosity and stability.

30
31 235 In addition to visual inspections of the emulsion stability, the drops size of the dispersed
32
33
34 236 aqueous phase was measured after 10 times dilution with oil by optical microscopy. Figure 2a
35
36 237 showed an image of a W/O emulsion stabilized by PGPR 90 at 6 g/L. High shear mixing led
37
38
39 238 to emulsions with a narrow size distribution and a mean diameter of the dispersed aqueous
40
41 239 phase drops of about 1.4 μm.

42
43
44 240
45
46 241 In order to confirm that it is a W/O emulsion, a drop of the emulsion was dispersed in water
47
48
49 242 (Figure 2b) and analyzed under optical microscopy. A double W/O/W emulsion was formed
50
51 243 by an oil continuous phase and a first dispersed CaCl₂ solution droplets internal phase
52
53 244 surrounded by a second dispersed CaCl₂ external phase.

54
55
56 245
57
58 246 **3.2. Characterization of components by TGA**

247 the Thermal degradation behavior of pure components that form the capsules (alginate,
248 calcium and sunflower oil) was performed and analyzed by TGA up to 800°C, with the idea
249 of identifying the degradation temperature of each component. Figure 3 showed the TGA
250 thermograms and derivative thermograms dTGA of sunflower oil, CaCl₂ and alginate
251 powders.

252 By analyzing the TGA of CaCl₂·2H₂O, a considerable weight loss was clearly observed
253 between 25°C and 130°C that was ascribed to the endothermic removal of crystalline and
254 loosely bound surface water, as it was also observed by Karunadasa et al. [19]. There was a
255 first endothermic dehydration at around 130 °C accounted for the emergence of monohydrate
256 calcium chloride (CaCl₂·H₂O) (Figure 3). A significant reduction in weight of calcium
257 chloride was observed during the second endothermic dehydration (between 150 and 220 °C,
258 dTGA curve, Fig. 3) that further ensured the complete removal of crystalline water from the
259 material. Although the magnitude of second endothermic dehydration was significantly larger
260 than the first one, it was concluded that the removal of crystalline water from the
261 monohydrate was rather difficult compare to the dihydrate calcium chloride (Fig. 3, dTGA
262 curve). This was a good indication of the strong association of crystalline water in
263 monohydrate that requires a considerable amount of thermal energy to eliminate it from the
264 monohydrate [19].

265 The TGA/dTGA curves for sunflower oil displayed two thermal decomposition steps in the
266 range of 300 to 510°C, with no residue remaining at 800°C (see Figure 3). It was observed
267 that the first step (300 to 420°C) corresponded to the decomposition of the polyunsaturated
268 fatty acids. During heating, the triglycerides, which form 96 to 98% of the edible oils, produce
269 volatile compounds, which are constantly removed by vapor generated during heating. These
270 products (dimers, trimers, polymers) are formed principally by thermal reactions of
271 unsaturated fatty acids, such as linoleic acid. The first step is the most important for the

272 thermal stability of edible oils, because this is the step where decomposition of the
273 unsaturated fatty acids begins. The thermal stability of sunflower oils is dependent on the
274 composition of the fatty acids, as it is influenced by artificial antioxidants [20]. The beginning
275 of oxidation in edible vegetable oils is characterized by absorption of oxygen through the fatty
276 acid chain, subsequently forming the oxidation product as peroxides. This behavior is
277 generally identified by an increase in the initial mass of the sample. The second step in the
278 thermal decomposition of sunflower oils (420 to 520°C) corresponds to the decomposition of
279 monounsaturated fatty acids such as oleic acid and saturated fatty acids, such as palmitic acid.
280 During this reaction, the double bonds are broken, causing the triglyceride molecules in the
281 edible vegetable oils to become saturated [20].

282 Figure 3 also showed the TGA and dTGA curves for the sodium alginate. It is shown that the
283 salt decomposed by dehydration followed by degradation to Na_2CO_3 and a carbonized
284 material that decomposed slowly from 550-750 °C in N_2 (Figure 3), as also noticed by other
285 authors [21-22].

286 Taking into account that the alginate content in the dried capsules as well as the degradation
287 peaks observed by dTGA curves are negligible, compared to the sunflower oil alone, it was
288 considered that temperature range of the oil degradation did not overlap with those of alginate
289 and CaCl_2 pure components. By this way, it was therefore possible to use this technique to
290 determine the oil content of the wet and dried capsules between 300 and 510°C.

291 **3.3. Microcapsules formation**

292 Based on Martins et al (2017b) previous results, the mechanism of capsule formation would
293 occur in three steps:

294 I- the Emulsion drops characterized by a continuous oil phase containing CaCl_2 solution
295 droplets contacted the alginate solution

296 II- ~~the~~ CaCl₂ solution droplets near the oil-alginate solution interface were able to migrate
1
2 297 from the emulsion to the alginate phase by a mechanism of diffusion/permeation through the
3
4
5 298 oil layer [23]
6

8 299 III- ~~the~~ Ca²⁺ ions cross-linked the alginate chains resulting in the formation of a membrane.
9

11 300 **3.3.1. Effect of curing time**

14 301 W/O emulsions containing 90 g/L of CaCl₂ and 6g/L of PGPR 90 were co-flowed with the
15
16
17 302 alginate-Tween 20 continuous phase in order to generate monodisperse W/O emulsion drops
18
19 303 that finally reached the alginate bath. These capsules were kept in contact with the alginate
20
21
22 304 bath by increasing curing time from 3 to 50 minutes. After these curing times, capsules were
23
24 305 filtered, rinsed with distilled water and stored in a CaCl₂ solution (15 g/L) at 4°C before ~~the~~
25
26 306 microscopy observations.
27

30 307 **3.3.1.1. Size of capsules and membrane thickness**

33 308 Microscopic observations revealed that spherical capsules with a well-defined alginate
34
35
36 309 membrane were collected in the alginate bath whatever the curing time (Figure 4).
37

39 310 Figure 5 showed the dependence of ~~the~~ capsule diameter and ~~the~~ membrane thickness with ~~the~~
40
41
42 311 curing time. The average diameter of alginate capsules ranged from 1.9 to 2.6 mm depending
43
44 312 on curing time (**significant differences at $p < 0.05$**), with a size polydispersity lower than 10%
45
46 313 (**data not shown**). Other authors also found that microcapsules produced using microfluidics
47
48
49 314 had extremely narrow size distributions [24]. Using droplets millifluidic process, capsule size
50
51 315 depends on droplet dimension before getting into contact with the alginate phase, ~~the~~ droplet
52
53
54 316 dimension depending on both the internal diameter of the Teflon tube (which was constant
55
56 317 and equal to 1.57 mm throughout the experimental assays) and the dispersed over continuous
57
58
59 318 flow rates ratio (also constant and equal to 0.4).

319 Membrane thickness measurements (made from pictures obtained by optical microscopy)
320 showed a curing time-dependent thickness of alginate capsules which increased with curing
321 time (from 98 ± 28 to 306 ± 21 μm at 3 and 45 minutes, respectively) (significant differences
322 at $p < 0.05$) (see Figure 5). The increase of the membrane thickness was significant at low
323 curing times and reached a pseudo-plateau at high curing times. The capsules reached
324 therefore the maximum of membrane thickness after 30 min of curing time. This result was
325 consistent with the increase of diffusion resistance and the decrease of calcium chloride
326 concentration in time [25]. Blandino *et al.* [26] obtained nearly the same evolution for the
327 thickness of gel layer capsules as a function of time for an alginate-CMC capsule system
328 where thickness was measured by cutting the capsules into halves and examining the
329 membranes with a microscope.

330 From Figures 4 and 5, it was concluded that capsule diameter and membrane thickness were
331 linearly dependent on curing time; in addition, membrane thickness reached a plateau at high
332 curing times due to restricted calcium diffusion. Martins *et al.* [11] checked that the emulsion
333 drop surface was surrounded by an oily layer that limited the contact of the CaCl_2 solution
334 droplets with the external media. This external oil layer could act as a barrier hindering the
335 release of aqueous CaCl_2 droplets during the capsule production.

336 ***3.3.1.2. Capsules oil content***

337 In this study, droplets millifluidic was used as a rapidly expanding technology with a unique
338 ability to “package” materials in the form of millicapsules, and a natural polysaccharide from
339 brown seaweed as a stable container of sunflower oil. Therefore, it was very important to
340 ascertain the capacity of the polymeric matrix to hold the bioactive compounds.

341 Oil content was around 80% for all the analyzed dried millicapsules, a content quite high
342 compare to other encapsulation processes based on the external and on the internal gelation

343 mechanisms [27]. Once the emulsion was in contact with alginate, the process of membrane
344 formation occurred but the oil was already encapsulated. As the contribution of the membrane
345 weight was negligible with respect to the oil content, the increase in the curing time did not
346 represent a substantial change of the final core content (Figure 2, supplementary data). This
347 was the main reason why, despite the high reproducibility of the method to produce
348 monodisperse core-shell capsules, the oil content was always constant.

349 ***3.3.1.3. Mechanical properties of capsules***

350 Mechanical behavior is a very important characteristic, as capsules or beads have to withstand
351 mechanical stress caused by shear forces, compression or osmotic pressure, during the
352 manufacture of the food product, packaging, transport, storage, handling and consumption. In
353 particular, mechanical stiffness of alginate gel millicapsules, controlled by the strength and
354 number of cross-links between the polymer chains, influences the permeability of the
355 capsules, property highly important for solutes diffusion in cell encapsulation [28].

356 Numerous methods exist to determine the mechanical properties of capsules [29]. A well-
357 established method consists in uniaxial compression of a single capsule between two plates
358 and recording the force-displacement curve. Compression experiments are generally
359 sufficiently sensitive to characterize the mechanical behavior of liquid-filled alginate
360 capsules.

361 Elastic characteristics such as Young modulus are calculated from the initial slope of the
362 force-displacement curve by means of different approaches (e.g. Hertz model) [15, 24, 29,
363 30]. The advantage of single-bead measurement consists in detailed information of a single
364 object and variations between beads of one production batch can be thoroughly analyzed.
365 Otherwise, it is time consuming to collect substantial, statistical significant data [24, 31].

366

367 Alginate capsules are sensitive to deformations that may lead to their rupture or to undesirable
1
2 368 early release of their content. It was demonstrated from the analyses of force-indentation
3
4
5 369 curves obtained by AFM that alginate microspheres, beads and capsules had almost a pure
6
7 370 elastic behavior [32]. Surface Young modulus, or two-dimensional Young modulus, is
8
9
10 371 therefore an interesting parameter to quantify mechanical stability as it describes the elastic
11
12 372 properties of the capsules. From Equation (1), compression curves at small deformations were
13
14 373 linearly fitted in order to extract the two-dimensional (or surface) Young modulus E_s under
15
16
17 374 point loading close to the pole [15]:

18
19 375

$$F = \frac{4E_s m}{a\sqrt{3(1-\nu_s^2)}} dD \quad \text{Eq. 1}$$

20
21
22 376
23
24
25
26
27 377 In this equation, dD is the capsule displacement, F the measured force, E_s the surface Young
28
29 378 modulus, m the membrane thickness, a the radius of the capsule and ν_s the surface Poisson
30
31
32 379 ratio for which a value of 1/3 was assumed according to [25]. Other more complicated
33
34 380 methods of resolution by solving numeric calculations were presented in further citations [33,
35
36
37 381 34]. It was therefore important to recall that Eq. 1 only holds for spherical capsules in the very
38
39 382 small deformations regime.

40
41
42 383 A typical force (F) versus displacement (D) curve from compression of single dry and wet
43
44 384 alginate capsules were shown in **Figure 6**. As expected, the drying step induced an
45
46 385 approximately ten-fold reduction of the membrane thickness due to water loss and,
47
48
49 386 consequently, a huge increase of the surface Young modulus was noticed (see Table 1 and
50
51 387 **Figure 6**).

52
53
54 388 Figure 7 summarized surface Young modulus values of wet alginate capsules in function of
55
56 389 curing time (calculated by linear regression from compression curves at small displacements).
57
58
59 390 Surface Young moduli (**significant differences at $p < 0.05$**) approximately two-fold decreased

391 with increasing curing time, result in apparent contradiction with the increase of membrane
1
2 392 thickness with curing time. The Surface Young modulus values were in the same order of
3
4
5 393 magnitude that those obtained by Leick et al. [25] for alginate capsules obtained from two
6
7 394 types of alginate with different guluronic acid content: 6.5 N/m and 32.9 N/m, for the higher
8
9 395 and lower content of guluronic acid, respectively. From another study, Leick et al. [35] found
10
11 396 surface Young moduli of 10 and 5 N/m for pure alginate and alginate/PLL capsules taking a
12
13 397 Poisson ratio of zero, values consistent with the assumption of a lower cross-linking degree of
14
15 398 the alginate/PLL composite capsules. More interestingly, each additional electrolyte
16
17 399 adsorption layer (PLL or alginate) gave roughly an increase of the surface Young modulus of
18
19 400 about 5 N/m for the investigated alginate/PLL/alginate capsule system under the used
20
21 401 preparation conditions. Messaoud et al. [36] investigated the influence of pH for alginate
22
23 402 capsules, and they obtained surface Young moduli ranging from 14.9 to 22 N/m at pH 7 and
24
25 403 pH 2, respectively, indicating that a decrease in pH resulted in a stiffer alginate membrane.
26
27 404 The same pH-dependence thickness of composite pectinate/shellac capsules was found by
28
29 405 Leick et al. [37]. The dependence of the pH value for composite capsules on the deformation
30
31 406 was also consistent with variations of the membrane thickness. Membranes prepared with
32
33 407 additional shellac seemed to be thinner but stiffer. Furthermore, at the lowest pH value, the
34
35 408 highest amount of precipitated shellac led to the strongest inhibition of calcium ion diffusion
36
37 409 and therefore to the thinnest membranes.

46 410 Figure 8 displayed the evolution of the surface Young modulus with the capsule dimensions.
47
48 411 Apart from the slight decrease of surface Young modulus with the increase of wet capsule
49
50 412 diameter (Figure 8a) and the linear decay with membrane thickness (Figure 8b), it was noticed
51
52 413 that the surface Young modulus linearly increased with the diameter / thickness ratio of
53
54 414 capsules (Figure 8c). Rachik et al. [14] reported that the increase in membrane thickness was
55
56 415 linked to an increase in intrinsic membrane rigidity as it was expected that the density of

416 crosslinking was larger in thicker membranes. Consequently, the surface Young modulus E_s
417 that measures the whole ability of the membrane to deform upon deformation increased.
418 Contrary, in our study, surface Young modulus ranged from 68 to 21 N/m at 3 and 50 min,
419 respectively, (see Table 1), indicating that an increase of curing time led to an increase of
420 membrane thickness (see Figure 8b) and to a decrease of the mechanical properties (lower
421 surface Young modulus E_s values) resulting in softer alginate membranes. This decrease of
422 the two-dimensional modulus could be explained by a higher hydration level of the membrane
423 leading therefore to a decrease of the crosslinking degree, i.e. the density of ~~covalent~~ ionic
424 bonds between Ca^{2+} and alginate would be smaller in the thicker membrane due to water
425 uptake. Following this hypothesis, ~~the~~ calcium content from the W/O droplets quickly
426 diffused from the emulsion-core to the alginate solution and remained constant with time.
427 This phenomenon was clearly seen on Figures 8b and 8c where a linear decrease was noticed
428 for the surface Young modulus with the increase of membrane thickness and diameter /
429 thickness ratio. This result therefore gave more confidence to the hypothesis of Martins et al.
430 [11] who clearly identified by optical microscopy that the emulsion drop surface was
431 surrounded by an oily layer that limited the contact of ~~the~~ CaCl_2 solution droplets with ~~the~~
432 alginate phase. This external oil layer therefore acted as a barrier hindering the release of
433 aqueous CaCl_2 droplets during curing time.

434 435 **3.3.2. Effect of cation concentration**

436 In order to understand the effect of the storage solution on both membrane thickness and
437 surface Young modulus, capsules with a curing time of 30 min in an alginate bath were stored
438 in NaCl solution (1.5%wt) and several CaCl_2 solutions at concentrations ranging from 0 to
439 1.5%wt.

440 Microscopic observations were performed during a 48 h period to see the evolution of
1
2 441 membrane thickness (see Figure 9) (significant differences at $p < 0.05$). The first important
3
4 442 observation was that membrane thickness was higher when capsules were stored in distilled
5
6
7 443 water contrary to CaCl_2 solutions, result in agreement with the swelling of alginate membrane
8
9
10 444 in time. After 24 h of storage in CaCl_2 solution, the membrane thickness reached a plateau
11
12 445 whatever the CaCl_2 concentration (Figure 9). This result was in accordance with the absence
13
14 446 of diffusion of calcium ions from inside to the outside of the capsules and conversely
15
16
17 447 hindering the growth of alginate membrane in time. Finally, the storage of capsules in NaCl
18
19 448 solution led to a huge increase of membrane thickness in time, result in accordance with the
20
21
22 449 competition of calcium and sodium ions for alginate cross-linking and the resulting swelling
23
24 450 of alginate membrane due to the loss of calcium ions in the cross-links. The membrane
25
26
27 451 thickness measured at 48 h was used to evaluate the mechanical properties immediately after
28
29 452 the microscopic observations.
30
31 453 Table 2 showed the surface Young modulus values obtained from the analyses of the force
32
33
34 454 displacement curves. Surface Young modulus values were constant with an average value of
35
36 455 35 N/m whatever the calcium concentration used for the storage of alginate capsules, result in
37
38
39 456 agreement with the constant value of membrane thickness ($Mt \sim 360.3 \mu\text{m}$).
40
41 457 In order to eliminate the influence of membrane thickness on the surface Young modulus and
42
43
44 458 to facilitate the comparison between the different storage conditions, Table 2 also showed a
45
46 459 normalized Surface Young modulus defined as E_s/Mt . Even if it was confirmed that E_s/Mt
47
48
49 460 was constant whatever the calcium concentration used for capsules storage with $E_s/Mt \sim$
50
51 461 0.099, it was noticed that E_s/Mt two-fold decreased when capsules were stored in distilled
52
53
54 462 water and more important thirty three-fold decreased when capsules were stored in NaCl. The
55
56 463 increase of membrane thickness according to the decrease of E_s/Mt was of 33% in water and
57
58
59 464 of 107% in NaCl. Swelling process of alginate membrane could be evoked to explain the

465 increase of membrane thickness and therefore the decrease of surface Young modulus
466 depending on ~~the~~ storage conditions. This swelling process would be considerably favored in
467 presence of sodium salt compare to distilled water in particular due to the competition of
468 sodium and calcium ions for the guluronic acid residues on alginate chains favoring the large
469 decrease of cross-linking density in the alginate network and the huge increase of water
470 uptake within the membrane. Authors recently clearly demonstrated, using spinning drop
471 techniques, capsule squeezing experiments and interfacial shear rheology, changes in the
472 mechanical properties of alginate membrane after storage of capsules in calcium or sodium
473 salt solutions [38]. For instance, surface Young modulus determined by compression
474 experiments decreased from 41 to 6.0 N/m when capsules were stored in calcium and sodium
475 salt solutions, respectively. This effect was ascribed to changes of the cross-linking density
476 and therefore a reduction of cross-linking density due to ion exchange in the case of sodium
477 salt. It was also found recently that sugar concentrations above 15% (wt) reduced extensibility
478 of alginate molecules and lead to a more open or less connected gel network with aggregated
479 alginate strands [39]. In addition, authors also demonstrated the high swelling rate of alginate
480 capsules without sugar in presence of simulated intestinal fluid, fluid containing sodium
481 hydroxide and potassium phosphate. The effect of sodium salt could be similar to sugar or
482 intestinal fluid by changing the alginate network and in particular pore diameter allowing a
483 higher uptake of water in the membrane. Pore diameters ranging from 2.52 to 3.94 nm were
484 recently reported, **using low temperature N2 adsorption-desorption analysis**, depending on
485 alginate sample and sodium content [40].

487 CONCLUSIONS

488 Stable W/O emulsions with a narrow size distribution were obtained by homogenization using
489 PGPR 90 as surfactant. Spherical millimetric capsules were successfully obtained by inverse

490 gelation using droplets-based millifluidic. The effect of curing time and cation concentration
491 on the oil content, structure and mechanical properties of capsules was analyzed. Alginate
492 membrane thickness increased with curing time in the collecting alginate bath until a plateau
493 was reached, in close relation with the presence of an oily layer surrounded the surface of
494 W/O emulsion drops therefore limiting the contact of ~~the~~ CaCl₂ solution droplets with ~~the~~
495 alginate phase. This external oil layer therefore acted as a barrier hindering the release of
496 aqueous CaCl₂ droplets during curing time. Compression experiments on individual capsules
497 revealed that alginate membrane thickness was inversely related to its mechanical properties,
498 i.e. the thicker membrane, the lower surface Young modulus. This result was explained in
499 terms of enhanced swelling properties of alginate membrane with curing time or storage
500 conditions. Drying capsules led to much more resistant membranes due to the loss of water.
501 Oil loading of 80 wt% was obtained for dry capsules whatever the conditions used.

503 **Acknowledgements**

504 We kindly acknowledge the supply of PGPR 90 by Danisco (France), the supply of alginate
505 by Cargill (France), the technical assistance of Jean-Eudes Megret for compression
506 experiments, and the financial support of one author (Mariana Pereda) by the National
507 Research Council of Republic Argentina (CONICET) through the program “Becas en el
508 Exterior para Jóvenes Investigadores del CONICET” (Argentina).

a,b,c,d Different letters in the same column indicate significant differences among the different storage solutions (p < 0.05).

685 **Figure captions**

1 686

2 687 Figure 1. Images of W/O emulsions as function of storage time.

3 688

4 689 Figure 2. Micrographs of a) oil diluted W/O emulsion (scale bar 25 μm) and b) water diluted W/O
5 690 emulsion (scale bar 250 μm) resulting in the formation of a double W/O/W emulsion.

6 691

7 692 Figure 3. Thermogravimetric analyses of sunflower oil, alginate and calcium chloride powders used to
8 693 prepare capsules.

9 694

10 695 Figure 4. Micrographs of wet capsules as function of curing time. Scale bar 250 μm .

11 696

12 697 Figure 5. Diameter d (mm) and membrane thickness Mt (μm) of wet capsules as function of curing
13 698 time. **Solid line corresponded to the fitting of the data by a linear function; dotted line was just eye-**
14 699 **guide. At the 0.05 level, the populations means were significantly different.**

15 700

16 701 Figure 6. Compression behavior of wet and dry capsules. Curing time = 30 min.

17 702

18 703 Figure 7. **Surface Young modulus (N/m)** of wet capsules as function of curing time. **At the 0.05 level,**
19 704 **the populations means were significantly different.**

20 705

21 706 Figure 8. Evolution of the surface Young modulus with wet capsule dimensions: a) diameter; b)
22 707 membrane thickness and c) diameter/thickness ratio.

23 708

24 709 Figure 9. Evolution of the membrane thickness after different storage times in distilled water, CaCl_2 or
25 710 NaCl solutions. Curing time in alginate solution = 30 min. **At the 0.05 level, the populations means**
26 711 **were significantly different.**
