34

35 **Abstract**

36 Clumping index (CI) is a measure of foliage aggregation relative to a random distribution
37 of leaves in space. The CI can help with estimating fractions of sunlit and shaded leaves
38 for a given leaf area index (LAI) value. Both the CI and LAI can be obtained from global
39 Earth Observation data from sensors such as the Moderate Resolution Imaging
40 Spectrometer (MODIS). Here, the **synergy** between a MODIS-based CI and a MODIS LAI
41 product is examined using the theory of spectral invariants, also referred to as photon
42 recollision probability (p -theory'), along with raw LAI-2000/2200 Plant Canopy Analyzer
43 data from 75 sites distributed across a range of plant functional types. The p -theory
44 describes the probability (p -value) that a photon, having intercepted an element in the
45 canopy, will recollide with another canopy element rather than escape the canopy. We
46 show that empirically-based CI maps **can be integrated** with the MODIS LAI product. Our
47 results indicate that it is feasible to derive **approximate** p -values for any location solely
48 from Earth Observation data. This **approximation** is relevant for future applications of
49 the photon recollision probability concept for global and local monitoring of vegetation
50 using Earth Observation data.

51

52 **Keywords:** Photon recollision probability; Foliage clumping index; Leaf area index; Multi-
53 angle remote sensing

54

55

56 **1. Introduction**

57 Clumping index (CI) is a measure of foliage aggregation relative to a random
58 distribution of leaves in space (Nilson, 1971; Chen and Black, 1992). The CI is an
59 important factor for the correct quantification of true leaf area index (LAI). The CI is also
60 needed for estimating fractions of sunlit and shaded leaves in the canopy (Norman,
61 1982) - an effective way for upscaling from leaf to canopy for modeling vegetation
62 photosynthesis (Bonan et al., 2014; He et al., 2017; Jiang and Ryu, 2016). Global and
63 regional scale CI maps have been generated from various multi-angle sensors (e.g. He et
64 al., 2012; Pisek et al., 2010; 2013a; Wei and Fang, 2016) based on an empirical
65 relationship with the normalized difference between hotspot and darkspot (NDHD)
66 index (Chen et al., 2005). Ryu et al. (2011) suggested that the adequate representation
67 of canopy radiative transfer, important for the simulation of gross primary productivity
68 and evapotranspiration (Baldocchi and Harley, 1995), is possible by integrating CI with
69 incoming solar irradiance and LAI from Moderate Resolution Imaging Spectrometer
70 (MODIS) land and atmosphere products. It should be noted that the MODIS LAI/FPAR
71 product (MOD15A2H) uses internal a set of non-empirical, stochastic equations for the
72 parameterization of foliage clumping (Shabanov et al., 2003). Our objective is to find out
73 if the MODIS LAI product with its non-empirical, stochastic clumping parameterization
74 can be used together with empirically-based CI maps, e.g. for the calculation of
75 sunlit/shaded fractions of LAI.

76 Here, we assess the synergy between a MODIS-based CI (He et al., 2012) and a
77 MODIS LAI product (Yan et al., 2016a,b) using the theory of spectral invariants or 'p-
78 theory' (Knyazikhin et al., 1998) along with raw LAI-2000/2200 Plant Canopy Analyzer

79 (PCA; LI-COR Biosciences, Lincoln, NE, USA) data from 75 sites surveyed across a range
80 of plant functional types (PFTs). The p -theory predicts that the amount of radiation
81 scattered (reflected or transmitted) within a canopy depends only on the wavelength
82 and the spectrally invariant canopy structural parameter p . It can be interpreted as the
83 probability of a photon, having intercepted an element in the canopy, to recollide with
84 another canopy element rather than escape the canopy (Smolander and Stenberg,
85 2005). The parameter p is linked to the foliage clumping (Stenberg et al., 2016).
86 Simulation studies by Möttus et al. (2009) and Smolander and Stenberg (2005) showed
87 the recollision probability is closely related to LAI, with p -LAI relationships varying with
88 the degree of clumping in the spatial distribution of leaf (needle) area. At a fixed LAI, p -
89 value is larger the more aggregated the leaves in a canopy, or the smaller the canopy CI.
90 The p -theory is intuitive and connected to the radiative transfer theory through the
91 eigenvalues of the radiative transfer equation (Knyazikhin et al., 1998). Stenberg et al.
92 (2016) provide an excellent review of the photon recollision probability concept in
93 modelling the radiation regime of canopies.

94

95 **2. Materials and methods**

96 2.1 Method

97 Stenberg (2007) proposed to approximate a photon recollision probability for a
98 canopy (p -value) from the Plant Canopy Analyzer (PCA) as:

$$99 \quad p = 1 - (i_0 / LAI_{true}) \quad (1)$$

100 where p is photon recollision probability, LAI_{true} is true leaf area index, and i_0 is canopy
 101 interceptance (the portion of the incoming radiation (photons) that is intercepted by the
 102 leaves), which can be expressed as:

$$103 \quad i_0 = 1 - t_0 \quad (2)$$

104 where i_0 and t_0 are canopy interceptance and transmittance under diffuse, isotropic
 105 illumination conditions with constant directional intensity (Stenberg, 2007). Both i_0 and
 106 t_0 describe first interactions (with the canopy or the ground) only, and do not include
 107 photons which escape or interact again after being scattered from a leaf or the ground
 108 (Stenberg, pers. comm). Stenberg (2007) and Smolander and Stenberg (2005) further
 109 assume the canopy to have spherical leaf/shoot orientation and to be bounded
 110 underneath by a non-reflecting surface. t_0 is obtained as:

$$111 \quad t_0 = \overline{cgf} \quad (3)$$

112 where \overline{cgf} is the canopy gap fraction at zenith angle θ (averaged over azimuth angle
 113 and horizontal area). Eqs. (1,2) can be combined to give:

$$114 \quad i_0 = 1 - \overline{cgf} \quad (4)$$

115 It should be noted that p as defined by Stenberg (2007) is a canopy structural
 116 characteristic which is independent of the above canopy radiation conditions. The PCA-
 117 based LAI estimate (LAI_{PCA}) is calculated here as the mean of the logarithms of the gap
 118 fraction values with clumping effects partially considered (Ryu et al., 2010):

$$119 \quad LAI_{PCA} = \frac{1}{n} \sum_{i=1}^n \ln \left(\frac{1}{i_0} \right) \quad (5)$$

120 For the coniferous sites, the PCA estimate (LAI_{PCA}) is further converted to true LAI using
121 a shoot-scale grouping correction factor γ_E ($LAI_{true}=LAI_{PCA}*\gamma_E$) before calculating p
122 (Rautiainen et al., 2009).

123 Alternatively, t_0 can be also estimated for an effective zenith angle θ as a
124 function of LAI, mean projection of unit foliage area (G) (Ross, 1981), and clumping
125 index (CI) (Chen et al., 2005):

$$126 \quad t_0(\theta)=\exp[-G(\theta)CI LAI_{true}/\cos\theta] \quad (6)$$

127 Combining Eqs. (1) and (2) with (6), photon recollision probability p can then be
128 calculated with CI and LAI estimated from Earth Observation data as:

$$129 \quad p=1-(1-\exp[-G(\theta)CI LAI_{true}/\cos\theta])/LAI_{true} \quad (7)$$

130 with $G(\theta)=0.5$ and θ set as 57.3° to minimize the uncertainty about leaf angle
131 orientation information (Pisek et al., 2013b) and assuming that t_0 in Eq. (2) for the upper
132 hemisphere can be approximated by $t_0(57.3^\circ)$. Eqs. (4) and (7) provide a simple way to
133 evaluate the synergy of MODIS LAI (Yan et al., 2016a) and CI (He et al., 2012) products
134 with independent PCA estimates. In case of needleleaf forests, Eq. (7) needs to be
135 further modified when used in combination with the MODIS LAI product (LAI_{MODIS}):

$$136 \quad p=1-(1-\exp[-G(\theta) CI \gamma_E LAI_{MODIS}/\cos\theta])/(LAI_{MODIS} \gamma_E) \quad (8)$$

137 as vegetation clumping is not accounted for at the shoot scale in the original MODIS LAI
138 product (Yan et al., 2016b).

139

140 2.2 MODIS LAI data

141 The current version of the MODIS LAI/FPAR product (MOD15A2H) is Collection 6
142 (C6) (Yan et al., 2016a). The main algorithm is based on look-up tables (LUTs) simulated
143 from a three-dimensional radiative transfer (3D RT) model (Knyazikhin et al., 1999;
144 Myneni et al., 2002). The algorithm finds the best LAI and FPAR estimates with biome-
145 specific LUTs using daily land surface Bi-directional Reflectance Factors (BRFs) along with
146 their uncertainties. A back-up empirical method utilizes relationships between the
147 Normalized Difference Vegetation Index and LAI/FPAR to produce lower quality LAI
148 estimates. The LAI value corresponding to the maximum FPAR is selected over the
149 compositing period of four or eight days. Vegetation clumping in the 3D RT is accounted
150 for at plant and canopy scales.

151 The most important improvement in MOD15A2H C6 compared to previous
152 versions is the increase from 1 km to 500 m spatial resolution. In addition, a new version
153 of MODIS surface reflectances (MOD09GA C6) is used to replace the previous 1 km
154 intermediate dataset (MODAGAGG). In C6 the 1 km static land cover input is replaced
155 with new multi-year MODIS land cover product (MCD12Q1) at 500 m resolution.

156 Only MODIS LAI retrievals produced with the main RT algorithm closest to the
157 date of PCA measurements (see Section 2.4) were used in this study.

158

159 2.3 MODIS CI data

160 He et al. (2012) derived a global CI map at 500 m spatial resolution using the red
161 band (620-670 nm) from the MODIS BRDF Model Parameters product (MCD43A1;
162 Schaaf et al., 2002). Since MODIS does not observe near the hotspot and the angular

163 kernels used to construct the MODIS BRDF product do not include the complete hotspot
164 physics and consistently underestimate the hotspot, He et al. (2012) developed an
165 approach to correct the MODIS hotspot magnitude with synchronous co-registered
166 POLDER-3 data. After the MODIS hotspot correction, CI is derived using two coefficients
167 calculated from the second-order polynomial fit of the tabulated relationship between
168 CI and NDHD by Chen et al. (2005). He et al. (2012) assigned a single annual CI value, the
169 median from its noisy seasonal trajectory, to each pixel in the final map. This global CI
170 map is provided using the same pixel grid and projection as the MODIS LAI product
171 (Section 2.2).

172

173 2.4 Plant Canopy Analyzer data

174 Ryu et al. (2010) compiled raw PCA instrument data from 41 sites distributed
175 across six plant functional types ranging from boreal to tropical ecoclimatic zones. PCA
176 data from 34 sites from their synthesis data set were retained after assessing their
177 suitability for our study (e.g. representativeness of the area at the scale of
178 corresponding overlapping 500 m MODIS pixel footprint verified with Google Earth
179 Engine (Gorelick et al., 2017); temporal overlap with MODIS LAI product) (Table 1). In
180 addition to the retained sites from Ryu et al. (2010), PCA measurements from 41
181 additional sites were included in this study. The available raw PCA data were used to
182 approximate p -value at each site using Eq. (4). The corresponding γ_E values for given
183 coniferous species were obtained from literature and are provided in Table 1.

184 Table 1. Characteristics and results for 75 sites with raw PCA measurements. PFT is plant
185 functional type. Lat is latitude (in degrees). Lon is longitude (in degrees). PCA is Plant

186
187

Canopy Analyzer. LAI_{PCA} is LAI estimate from PCA data. p is the photon recollision probability. γ_E is the needle-to-shoot area ratio.

200

The relationship between LAI and photon recollision probability p approximated with PCA data using Eq. (4) is shown in Fig. 1. The nature of the p -LAI_{PCA} relationship is different between evergreen needleleaf (ENF) and other PFTs due to the inclusion of the shoot-scale correction factor (Chen, 1996). Compared to Rautiainen et al. (2009), the p -values representing needleleaf stands with greater variety of tree species were more dispersed. Our results support the notion by Rautiainen et al. (2009) that establishing species-specific p -LAI_{PCA} functions would require further research on the role of shoot-scale (shoot level) clumping and its documented variability between species (e.g. Chen et al., 2006; Stenberg et al., 1999; 2001) on photon recollision probability.

201

202 | **Fig. 1.** Relationship between Plant Canopy Analyzer (PCA)-derived leaf area index
 203 (LAI_{PCA}) and approximated photon recollision probability p . The abbreviations used in
 204 the figure legend are explained in the caption of Table 1.
 205

206

207 | **Fig. 2.** Comparison between the transmittance (t_0 ; Eq. (3)) and gap fraction from the
 208 fourth ring of Plant Canopy Analyzer (PCA) data.

209

210 Eq. (7) assumes that t_0 in Eq. (3) for the upper hemisphere can be approximated

211 by $t_0(57.3^\circ)$. A regression between the gap fraction from the fourth ring (47–58° from

212 zenith) and t_0 obtained from all five rings (Eq. (3)) for all sites is shown in Fig. 2. The tight

213 linear relationship close to the 1:1 line indicates that this ring alone (or 57.3° as its

214 representative) is indeed a reasonable approximation for t_0 of the upper hemisphere,

215 while simultaneously reducing the uncertainty introduced through an assumed leaf
 216 inclination angle distribution. It should be noted that previous research by Leblanc and
 217 Chen (2001) also found that the fourth ring itself provides a good approximation of
 218 LAI_{PCA} under both direct and diffuse light conditions.

219 Fig. 3A shows a strong linear relationship ($R^2=0.95$; Mean Absolute Error (MAE)=
 220 0.018; intercept 0.0043) between the p -values derived from Eqs. (4) and (7)

221

222 | **Fig. 3.** Relationships between photon recollision probabilities p derived with Eqs. (4) and
 223 (7) using Plant Canopy Analyzer (PCA) data (A) and MODIS LAI C6 product (B) as LAI
 224 input into Eq. (7).

225

226 using the PCA and γ_E data from Table 1 as the source of information about LAI, and CI
 227 values retrieved from He et al. (2012). Fig. 3A confirms the agreement between the two
 228 approaches (Eqs. (4) and (7)) to obtain p -value. The observed variation stems mainly
 229 from the uncertainty in G-function, CI values and approximation of $t_0(57.3^\circ)$ to t_0 of the
 230 upper hemisphere (Fig. 2). The clumping may change with season (Sprintsin et al., 2011;
 231 Pisek et al., 2015; Lang et al., 2017), while He et al. (2012) provide only the seasonal
 232 trajectory median value.

233 The linear relationship close to the 1:1 line (slope 1.0093; intercept -0.034)
 234 between the p -values derived from PCA and MODIS-only data (Fig. 3B) suggests a
 235 general compatibility of MODIS LAI and CI maps by He et al. (2012). Our results supports
 236 that a) the MODIS algorithm indeed uses the recollision probability to account for
 237 clumping, and b) the approach integrating the empirically based CI information with
 238 MODIS LAI suggested by Ryu et al. (2011) appears to be feasible. The difference
 239 between Figs. 3A and 3B is the inclusion of the MODIS LAI product in the latter one.
 240 Since the clumping in MODIS LAI is accounted for at the plant and canopy scales only,
 241 knowledge about the shoot-scale grouping correction factor γ_E is needed to retrieve the
 242 non-underestimated p -values in case of needleleaf forests.
 243

244
 245 | **Fig. 4.** Relationship between Plant Canopy Analyzer (PCA)-derived leaf area index
 246 (LAI_{PCA}) and MODIS LAI C6 product (LAI_{MODIS}). Both PCA and MODIS LAI data are not
 247 corrected for the shoot-scale grouping correction factor γ_E .
 248

249 Fig. 4 shows the scatterplot between LAI estimates from PCA and MODIS LAI C6
 250 product. The increase in mean absolute error in Fig. 3B (MAE=0.049) compared to Fig.
 251 3A (MAE=0.018) is linked to the different estimates and sources of LAI information for

252 Eq. (4) (PCA) and Eqs. (7) and (8) (MODIS LAI) as illustrated in Fig. 4. Furthermore, Fig. 1
253 shows that accurate LAI information for photon recollision probability estimation is
254 particularly critical at lower LAI values. Since reflectance values are not saturated within
255 LAI range of 0-2, LAI algorithms perform well within this domain (Yan et al., 2016b) and
256 should be able to provide high quality input data. Importantly, it should be verified if the
257 LAI input indeed corresponds to true LAI.

258 Our findings illustrate that it might be possible to obtain approximate p -values
259 for any location solely from Earth Observation data, given availability of high quality LAI
260 retrievals. In the future, the relationship could be possibly strengthened by further
261 improved CI retrieval algorithms from Earth Observation data (e.g. Wei and Fang, 2016),
262 by accounting for seasonal variation of clumping (He et al., 2016) and by knowing site
263 specific G-function values (Raabe et al., 2015). It is envisioned that our findings provide a
264 stimulus for future applications of the photon recollision probability concept for global
265 and local monitoring of vegetation using Earth Observation data (Stenberg et al., 2016).

266

267 **4. Conclusion**

268 Our results indicate that the integration of a MODIS LAI product with empirically-
269 based CI maps is feasible. Their synergy was assessed using the p -theory along with raw
270 LAI-2000/2200 Plant Canopy Analyzer data gathered across a wide range of plant
271 functional types. Importantly, for the first time it is shown that it might be possible to
272 obtain approximate p -values for any location solely from Earth Observation data. This
273 approximation is relevant for future applications of photon recollision probability

274 concept for global and local monitoring of vegetation using Earth Observation data
275 (Stenberg et al., 2016).

35 **Abstract**

36 Clumping index (CI) is a measure of foliage aggregation relative to a random distribution
37 of leaves in space. The CI can help with estimating fractions of sunlit and shaded leaves
38 for a given leaf area index (LAI) value. Both the CI and LAI can be obtained from global
39 Earth Observation data from sensors such as the Moderate Resolution Imaging
40 Spectrometer (MODIS). Here, the synergy between a MODIS-based CI and a MODIS LAI
41 product is examined using the theory of spectral invariants, also referred to as photon
42 recollision probability (*p*-theory), along with raw LAI-2000/2200 Plant Canopy Analyzer
43 data from 75 sites distributed across a range of plant functional types. The *p*-theory
44 describes the probability (*p*-value) that a photon, having intercepted an element in the
45 canopy, will recollide with another canopy element rather than escape the canopy. We
46 show that empirically-based CI maps can be integrated with the MODIS LAI product. Our
47 results indicate that it is feasible to derive approximate *p*-values for any location solely
48 from Earth Observation data. This approximation is relevant for future applications of
49 the photon recollision probability concept for global and local monitoring of vegetation
50 using Earth Observation data.

51

52 **Keywords:** Photon recollision probability; Foliage clumping index; Leaf area index; Multi-
53 angle remote sensing

54

55

56 **1. Introduction**

57 Clumping index (CI) is a measure of foliage aggregation relative to a random
58 distribution of leaves in space (Nilson, 1971; Chen and Black, 1992). The CI is an
59 important factor for the correct quantification of true leaf area index (LAI). The CI is also
60 needed for estimating fractions of sunlit and shaded leaves in the canopy (Norman,
61 1982) - an effective way for upscaling from leaf to canopy for modeling vegetation
62 photosynthesis (Bonan et al., 2014; He et al., 2017; Jiang and Ryu, 2016). Global and
63 regional scale CI maps have been generated from various multi-angle sensors (e.g. He et
64 al., 2012; Pisek et al., 2010; 2013a; Wei and Fang, 2016) based on an empirical
65 relationship with the normalized difference between hotspot and darkspot (NDHD)
66 index (Chen et al., 2005). Ryu et al. (2011) suggested that the adequate representation
67 of canopy radiative transfer, important for the simulation of gross primary productivity
68 and evapotranspiration (Baldocchi and Harley, 1995), is possible by integrating CI with
69 incoming solar irradiance and LAI from Moderate Resolution Imaging Spectrometer
70 (MODIS) land and atmosphere products. It should be noted that the MODIS LAI/FPAR
71 product (MOD15A2H) uses internal a set of non-empirical, stochastic equations for the
72 parameterization of foliage clumping (Shabanov et al., 2003). Our objective is to find out
73 if the MODIS LAI product with its non-empirical, stochastic clumping parameterization
74 can be used together with empirically-based CI maps, e.g. for the calculation of
75 sunlit/shaded fractions of LAI.

76 Here, we assess the synergy between a MODIS-based CI (He et al., 2012) and a
77 MODIS LAI product (Yan et al., 2016a,b) using the theory of spectral invariants or 'p-
78 theory' (Knyazikhin et al., 1998) along with raw LAI-2000/2200 Plant Canopy Analyzer

79 (PCA; LI-COR Biosciences, Lincoln, NE, USA) data from 75 sites surveyed across a range
80 of plant functional types (PFTs). The p -theory predicts that the amount of radiation
81 scattered (reflected or transmitted) within a canopy depends only on the wavelength
82 and the spectrally invariant canopy structural parameter p . It can be interpreted as the
83 probability of a photon, having intercepted an element in the canopy, to recollide with
84 another canopy element rather than escape the canopy (Smolander and Stenberg,
85 2005). The parameter p is linked to the foliage clumping (Stenberg et al., 2016).
86 Simulation studies by Möttus et al. (2009) and Smolander and Stenberg (2005) showed
87 the recollision probability is closely related to LAI, with p -LAI relationships varying with
88 the degree of clumping in the spatial distribution of leaf (needle) area. At a fixed LAI, p -
89 value is larger the more aggregated the leaves in a canopy, or the smaller the canopy CI.
90 The p -theory is intuitive and connected to the radiative transfer theory through the
91 eigenvalues of the radiative transfer equation (Knyazikhin et al., 1998). Stenberg et al.
92 (2016) provide an excellent review of the photon recollision probability concept in
93 modelling the radiation regime of canopies.

94

95 **2. Materials and methods**

96 2.1 Method

97 Stenberg (2007) proposed to approximate a photon recollision probability for a
98 canopy (p -value) from the Plant Canopy Analyzer (PCA) as:

$$99 \quad p = 1 - (i_0 / LAI_{true}) \quad (1)$$

100 where p is photon recollision probability, LAI_{true} is true leaf area index, and i_0 is canopy
 101 interception (the portion of the incoming radiation (photons) that is intercepted by the
 102 leaves), which can be expressed as:

$$103 \quad i_0 = 1 - t_0 \quad (2)$$

104 where i_0 and t_0 are canopy interception and transmittance under diffuse, isotropic
 105 illumination conditions with constant directional intensity (Stenberg, 2007). Both i_0 and
 106 t_0 describe first interactions (with the canopy or the ground) only, and do not include
 107 photons which escape or interact again after being scattered from a leaf or the ground
 108 (Stenberg, pers. comm). Stenberg (2007) and Smolander and Stenberg (2005) further
 109 assume the canopy to have spherical leaf/shoot orientation and to be bounded
 110 underneath by a non-reflecting surface. t_0 is obtained as:

$$111 \quad t_0 = 2 \int_0^{\pi/2} \overline{cgf}(\theta) \sin(\theta) \cos(\theta) d\theta \quad (3)$$

112 where \overline{cgf} is the canopy gap fraction at zenith angle θ (averaged over azimuth angle
 113 and horizontal area). Eqs. (1,2) can be combined to give:

$$114 \quad p = 1 - \frac{1 - 2 \int_0^{\pi/2} \overline{cgf}(\theta) \sin(\theta) \cos(\theta) d\theta}{LAI_{true}} \quad (4)$$

115 It should be noted that p as defined by Stenberg (2007) is a canopy structural
 116 characteristic which is independent of the above canopy radiation conditions. The PCA-
 117 based LAI estimate (LAI_{PCA}) is calculated here as the mean of the logarithms of the gap
 118 fraction values with clumping effects partially considered (Ryu et al., 2010):

$$119 \quad LAI_{PCA} = -2 \int_0^{\pi/2} \overline{\ln(cgf(\theta))} \sin(\theta) \cos(\theta) d\theta \quad (5)$$

120 For the coniferous sites, the PCA estimate (LAI_{PCA}) is further converted to true LAI using
121 a shoot-scale grouping correction factor γ_E ($LAI_{true}=LAI_{PCA}*\gamma_E$) before calculating p
122 (Rautiainen et al., 2009).

123 Alternatively, t_0 can be also estimated for an effective zenith angle θ as a
124 function of LAI, mean projection of unit foliage area (G) (Ross, 1981), and clumping
125 index (CI) (Chen et al., 2005):

$$126 \quad t_0(\theta)=\exp[-G(\theta)CI LAI_{true}/\cos\theta] \quad (6)$$

127 Combining Eqs. (1) and (2) with (6), photon recollision probability p can then be
128 calculated with CI and LAI estimated from Earth Observation data as:

$$129 \quad p=1-(1-\exp[-G(\theta)CI LAI_{true}/\cos\theta])/LAI_{true} \quad (7)$$

130 with $G(\theta)=0.5$ and θ set as 57.3° to minimize the uncertainty about leaf angle
131 orientation information (Pisek et al., 2013b) and assuming that t_0 in Eq. (2) for the upper
132 hemisphere can be approximated by $t_0(57.3^\circ)$. Eqs. (4) and (7) provide a simple way to
133 evaluate the synergy of MODIS LAI (Yan et al., 2016a) and CI (He et al., 2012) products
134 with independent PCA estimates. In case of needleleaf forests, Eq. (7) needs to be
135 further modified when used in combination with the MODIS LAI product (LAI_{MODIS}):

$$136 \quad p=1-(1-\exp[-G(\theta) CI \gamma_E LAI_{MODIS}/\cos\theta])/(LAI_{MODIS} \gamma_E) \quad (8)$$

137 as vegetation clumping is not accounted for at the shoot scale in the original MODIS LAI
138 product (Yan et al., 2016b).

139

140 2.2 MODIS LAI data

141 The current version of the MODIS LAI/FPAR product (MOD15A2H) is Collection 6
142 (C6) (Yan et al., 2016a). The main algorithm is based on look-up tables (LUTs) simulated
143 from a three-dimensional radiative transfer (3D RT) model (Knyazikhin et al., 1999;
144 Myneni et al., 2002). The algorithm finds the best LAI and FPAR estimates with biome-
145 specific LUTs using daily land surface Bi-directional Reflectance Factors (BRFs) along with
146 their uncertainties. A back-up empirical method utilizes relationships between the
147 Normalized Difference Vegetation Index and LAI/FPAR to produce lower quality LAI
148 estimates. The LAI value corresponding to the maximum FPAR is selected over the
149 compositing period of four or eight days. Vegetation clumping in the 3D RT is accounted
150 for at plant and canopy scales.

151 The most important improvement in MOD15A2H C6 compared to previous
152 versions is the increase from 1 km to 500 m spatial resolution. In addition, a new version
153 of MODIS surface reflectances (MOD09GA C6) is used to replace the previous 1 km
154 intermediate dataset (MODAGAGG). In C6 the 1 km static land cover input is replaced
155 with new multi-year MODIS land cover product (MCD12Q1) at 500 m resolution.

156 Only MODIS LAI retrievals produced with the main RT algorithm closest to the
157 date of PCA measurements (see Section 2.4) were used in this study.

158

159 2.3 MODIS CI data

160 He et al. (2012) derived a global CI map at 500 m spatial resolution using the red
161 band (620-670 nm) from the MODIS BRDF Model Parameters product (MCD43A1;
162 Schaaf et al., 2002). Since MODIS does not observe near the hotspot and the angular

163 kernels used to construct the MODIS BRDF product do not include the complete hotspot
164 physics and consistently underestimate the hotspot, He et al. (2012) developed an
165 approach to correct the MODIS hotspot magnitude with synchronous co-registered
166 POLDER-3 data. After the MODIS hotspot correction, CI is derived using two coefficients
167 calculated from the second-order polynomial fit of the tabulated relationship between
168 CI and NDHD by Chen et al. (2005). He et al. (2012) assigned a single annual CI value, the
169 median from its noisy seasonal trajectory, to each pixel in the final map. This global CI
170 map is provided using the same pixel grid and projection as the MODIS LAI product
171 (Section 2.2).

172

173 2.4 Plant Canopy Analyzer data

174 Ryu et al. (2010) compiled raw PCA instrument data from 41 sites distributed
175 across six plant functional types ranging from boreal to tropical ecoclimatic zones. PCA
176 data from 34 sites from their synthesis data set were retained after assessing their
177 suitability for our study (e.g. representativeness of the area at the scale of
178 corresponding overlapping 500 m MODIS pixel footprint verified with Google Earth
179 Engine (Gorelick et al., 2017); temporal overlap with MODIS LAI product) (Table 1). In
180 addition to the retained sites from Ryu et al. (2010), PCA measurements from 41
181 additional sites were included in this study. The available raw PCA data were used to
182 approximate p -value at each site using Eq. (4). The corresponding γ_E values for given
183 coniferous species were obtained from literature and are provided in Table 1.

184 Table 1. Characteristics and results for 75 sites with raw PCA measurements. PFT is plant
185 functional type. Lat is latitude (in degrees). Lon is longitude (in degrees). PCA is Plant

186
187

Canopy Analyzer. LAI_{PCA} is LAI estimate from PCA data. p is the photon recollision probability. γ_E is the needle-to-shoot area ratio.

3. Results and Discussion

192 The relationship between LAI and photon recollision probability p approximated
193 with PCA data using Eq. (4) is shown in Fig. 1. The nature of the p -LAI_{PCA} relationship is
194 different between evergreen needleleaf (ENF) and other PFTs due to the inclusion of the
195 shoot-scale correction factor (Chen, 1996). Compared to Rautiainen et al. (2009), the p -
196 values representing needleleaf stands with greater variety of tree species were more
197 dispersed. Our results support the notion by Rautiainen et al. (2009) that establishing
198 species-specific p -LAI_{PCA} functions would require further research on the role of shoot-
199 scale (shoot level) clumping and its documented variability between species (e.g. Chen
200 et al., 2006; Stenberg et al., 1999; 2001) on photon recollision probability.

201

202 **Fig. 1.** Relationship between Plant Canopy Analyzer (PCA)-derived leaf area index
 203 (LAI_{PCA}) and approximated photon recollision probability p . The abbreviations used in
 204 the figure legend are explained in the caption of Table 1.
 205

206

207 **Fig. 2.** Comparison between the transmittance (t_0 ; Eq. (3)) and gap fraction from the
 208 fourth ring of Plant Canopy Analyzer (PCA) data.

209

210 Eq. (7) assumes that t_0 in Eq. (3) for the upper hemisphere can be approximated

211 by $t_0(57.3^\circ)$. A regression between the gap fraction from the fourth ring (47–58° from

212 zenith) and t_0 obtained from all five rings (Eq. (3)) for all sites is shown in Fig. 2. The tight

213 linear relationship close to the 1:1 line indicates that this ring alone (or 57.3° as its

214 representative) is indeed a reasonable approximation for t_0 of the upper hemisphere,

215 while simultaneously reducing the uncertainty introduced through an assumed leaf
 216 inclination angle distribution. It should be noted that previous research by Leblanc and
 217 Chen (2001) also found that the fourth ring itself provides a good approximation of
 218 LAI_{PCA} under both direct and diffuse light conditions.

219 Fig. 3A shows a strong linear relationship ($R^2=0.95$; Mean Absolute Error (MAE)=
 220 0.018; intercept 0.0043) between the p -values derived from Eqs. (4) and (7)

221

222 **Fig. 3.** Relationships between photon recollision probabilities p derived with Eqs. (4) and
 223 (7) using Plant Canopy Analyzer (PCA) data (A) and MODIS LAI C6 product (B) as LAI
 224 input into Eq. (7).

225

226 using the PCA and γ_E data from Table 1 as the source of information about LAI, and CI
 227 values retrieved from He et al. (2012). Fig. 3A confirms the agreement between the two
 228 approaches (Eqs. (4) and (7)) to obtain p -value. The observed variation stems mainly
 229 from the uncertainty in G-function, CI values and approximation of $t_0(57.3^\circ)$ to t_0 of the
 230 upper hemisphere (Fig. 2). The clumping may change with season (Sprintsin et al., 2011;
 231 Pisek et al., 2015; Lang et al., 2017), while He et al. (2012) provide only the seasonal
 232 trajectory median value.

233 The linear relationship close to the 1:1 line (slope 1.0093; intercept -0.034)
 234 between the p -values derived from PCA and MODIS-only data (Fig. 3B) suggests a
 235 general compatibility of MODIS LAI and CI maps by He et al. (2012). Our results supports
 236 that a) the MODIS algorithm indeed uses the recollision probability to account for
 237 clumping, and b) the approach integrating the empirically based CI information with
 238 MODIS LAI suggested by Ryu et al. (2011) appears to be feasible. The difference
 239 between Figs. 3A and 3B is the inclusion of the MODIS LAI product in the latter one.
 240 Since the clumping in MODIS LAI is accounted for at the plant and canopy scales only,
 241 knowledge about the shoot-scale grouping correction factor γ_E is needed to retrieve the
 242 non-underestimated p -values in case of needleleaf forests.
 243

244
 245 **Fig. 4.** Relationship between Plant Canopy Analyzer (PCA)-derived leaf area index
 246 (LAI_{PCA}) and MODIS LAI C6 product (LAI_{MODIS}). Both PCA and MODIS LAI data are not
 247 corrected for the shoot-scale grouping correction factor γ_E .

248
 249 Fig. 4 shows the scatterplot between LAI estimates from PCA and MODIS LAI C6
 250 product. The increase in mean absolute error in Fig. 3B (MAE=0.049) compared to Fig.
 251 3A (MAE=0.018) is linked to the different estimates and sources of LAI information for

252 Eq. (4) (PCA) and Eqs. (7) and (8) (MODIS LAI) as illustrated in Fig. 4. Furthermore, Fig. 1
253 shows that accurate LAI information for photon recollision probability estimation is
254 particularly critical at lower LAI values. Since reflectance values are not saturated within
255 LAI range of 0-2, LAI algorithms perform well within this domain (Yan et al., 2016b) and
256 should be able to provide high quality input data. Importantly, it should be verified if the
257 LAI input indeed corresponds to true LAI.

258 Our findings illustrate that it might be possible to obtain approximate p -values
259 for any location solely from Earth Observation data, given availability of high quality LAI
260 retrievals. In the future, the relationship could be possibly strengthened by further
261 improved CI retrieval algorithms from Earth Observation data (e.g. Wei and Fang, 2016),
262 by accounting for seasonal variation of clumping (He et al., 2016) and by knowing site
263 specific G-function values (Raabe et al., 2015). It is envisioned that our findings provide a
264 stimulus for future applications of the photon recollision probability concept for global
265 and local monitoring of vegetation using Earth Observation data (Stenberg et al., 2016).

266

267 **4. Conclusion**

268 Our results indicate that the integration of a MODIS LAI product with empirically-
269 based CI maps is feasible. Their synergy was assessed using the p -theory along with raw
270 LAI-2000/2200 Plant Canopy Analyzer data gathered across a wide range of plant
271 functional types. Importantly, for the first time it is shown that it might be possible to
272 obtain approximate p -values for any location solely from Earth Observation data. This
273 approximation is relevant for future applications of photon recollision probability

274 concept for global and local monitoring of vegetation using Earth Observation data
275 (Stenberg et al., 2016).
