List of key words: Neonatal Intensive Care Unit, neuromotor and sensory disabilities, regionalization, evidence-based practices.

Supported by the French Institute of Public Health Research/Institute of Public Health and its partners the French Health Ministry, the National Institute of Health and Medical Research, the National Cancer Institute and the National Solidarity Fund for Autonomy; the National Research Agency through the French Equipex Program of Investments in the Future (ANR-11-EQPX-0038); the PremUp Foundation and Fondation pour la Recherche Médicale. The authors declare no conflicts of interest.

Objectives: To investigate the relation between neonatal intensive care unit (NICU) volume and survival, neuromotor and sensory disabilities at 2 years in very preterm infants.

Study design: The EPIPAGE-2 national prospective population-based cohort study was used to include 2447 babies born alive in 66 level III hospitals between 24 and 30 completed weeks of gestation in 2011. The outcome was survival without disabilities (levels 2-5 of the Gross Motor Function Classification System for cerebral palsy with or without unilateral or bilateral blindness or deafness). Units were grouped in quartiles according to volume, defined as the annual admissions of very preterm babies. Multivariate logistic regression analyses with population average models were used.

Results: Survival at discharge was lower in hospitals with lower volumes of neonatal activity (adjusted Odds Ratio 0.55, 95% Confidence Interval 0.33-0.91). Survival without neuromotor and sensory disabilities at two years increased with hospital volume, from 75% to 80.7% in the highest volume units. After adjustment for gestational age, small for gestational age, sex, maternal age, infertility treatment, multiple pregnancy, principal cause of prematurity, parental socioeconomic status and mother's country of birth, survival without neuromotor or sensory disabilities was significantly lower in hospitals with a lower volume of neonatal activity (adjusted Odds Ratio: 0.60, 95% confidence interval: 0.38-0.95) than in the highest quartile hospitals.

Conclusions: These results suggest that lower NICU volume is associated with lower survival without an increase in disabilities at 2 years. These results could be useful to generate improvements of perinatal regionalization.

Studies on regionalization of care have shown that mortality and severe neonatal morbidity of very low birth weight (VLBW) or very preterm (VPT) infants is lower when birth occurs at highly specialized hospitals.^{1,2} In most developed countries, it is recommended that

VLBW and VPT infants be born in specialized hospitals, generally designated as level III NICU hospitals ³⁻⁶.

Several studies have used hospital volume as an indicator of quality of care, and found that neonatal care at high-volume centers was associated with lower in-hospital mortality of VLBW and VPT infants ⁷⁻¹². However, some of these studies ^{11,12} also found a higher rate of severe neonatal morbidity in high volume hospitals, suggesting that their survivors may be at increased risk of disability in survivors. Studying longer term outcomes at 2 years is needed to determine whether the improvement in survival is followed by an increase in disabilities, providing valuable data for policy makers. In addition, it is worth testing whether these associations, seen primarily in the USA and in VLBW babies, exist in other countries and in VPT babies.

Perinatal regionalization has been in place in France since 1998 ¹³. Level III hospitals are defined as the highest level of care for preterm birth, and must have a Neonatal Intensive Care Unit (NICU), with the permanent presence of a qualified pediatrician trained in neonatology ¹⁴. In 2011, more than 80% of preterm births at 24⁺⁰ to 30⁺⁶ completed weeks of gestation were managed in a level III hospital ¹⁵. Previous French studies on regionalization are relatively outdated ^{16,17}, and none has investigated the effect of hospital volume.

Our objectives were to investigate the association of hospital volume with survival at discharge without severe neonatal morbidity, and survival at two years corrected age without neuromotor or sensory disabilities, among infants born at 24⁺⁰ to 30⁺⁶ weeks gestation in tertiary hospitals. We hypothesized that there would be higher survival without disability in VPT children born in hospitals that managed a high volume of premature newborns. We also investigated to

what extent the implementation of evidence-based practices varied by NICU volumes, potentially contributing to the health outcomes of VPT children.

Methods

The prospective population-based EPIPAGE 2 cohort (Etude Epidémiologique sur les Petits Âges Gestationnels) included all births occurring between 22 and 34 completed weeks' gestation in the 546 maternity units of 25 French regions from March to December in 2011. Recruitment lasted 8 months for infants born at 22 to 26 weeks and 6 months for those born at 27 to 31 weeks gestation. At 2 years corrected age, clinical data were collected through two standardized questionnaires: one completed by the referring pediatrician and the other by the parents. Details about ethical approval, the design and methods have been described previously^{18,19}.

We restricted our analyses to babies who were born alive in tertiary centers between 24 and 30 weeks gestation. We excluded neonates born after 30 weeks because the French recommendations allow for the management of these births in lower level hospitals. Newborns with lethal malformations (eg, anencephaly, and bilateral renal agenesis) or antenatal decision not to resuscitate were also excluded. All survivors were enrolled in follow-up if parents consented at 2 years corrected age.

Volume was defined as the total number of babies below 31 weeks gestation admitted to each hospital NICU during 2011. This number was obtained from the national hospital discharge database ("Programme de médicalisation du système d'information" used to determine the activity-based funding of French hospitals). We created four groups of hospitals using the 25th, 50th and 75th percentiles of volume. Hospitals in the highest quartile (Q4) were defined as high

volume units. Infants were allocated to the first level 3 unit in which they were hospitalized for 48 consecutive hours, or, when infants died in the delivery room, the NICU in connection with the obstetric unit.

Studied outcomes were survival at discharge, survival at discharge without severe neonatal morbidity, survival without sensorimotor disabilities at 2 years of age and psychomotor development outcome at 2 years. Severe neonatal morbidity was defined by one or more of the following complications: severe bronchopulmonary dysplasia (BPD), defined as administration of oxygen for at least 28 days plus need for 30% or more oxygen and/or mechanical ventilation or continuous positive airway pressure at 36 weeks postmenstrual age, severe intraventricular hemorrhage, defined as IVH associated with ventricular dilation (grade III, IV) and/or intraparenchymal hemorrhage, cystic periventricular leukomalacia, Bell's stage II or III necrotizing enterocolitis, and stage 3 or higher retinopathy of prematurity (ROP) ¹⁸.

Neuromotor and sensory disabilities included two outcomes: cerebral palsy and sensory disability. We used the diagnostic criteria previously established by the Surveillance of Cerebral Palsy in Europe (SCPE) network to define cerebral palsy ²⁰, and the five level Gross Motor Function Classification System (GMFCS) to classify motor ability ²¹. A child had a disability if he/she had cerebral palsy, GMFCS level 2-5, or unilateral or bilateral deafness or blindness. Psychomotor development outcome at two years was assessed using the second version of the Ages and Stages Questionnaire (ASQ) ²², and we analyzed the data if parents filled out this document when their child was between 22 and 26 months corrected age and if the child did not have cerebral palsy or sensory impairments. ASQ evaluates five domains of child development: communication, gross motor, fine motor, problem-solving and personal-social. We considered a

child as below threshold if he/she scored lower than 2 standard deviations from the mean in at least one domain ²².

We considered the following maternal characteristics: maternal age, maternal country of birth, and parents' socioeconomic status (the highest occupational status of the mother and the father, or mother only if a single parent). Pregnancy characteristics were: parity, infertility treatment, multiple pregnancy, antenatal steroids, antenatal transfer, hospital admission less than 24 hours before delivery, principal cause of prematurity (classified as preterm labor, preterm premature rupture of membranes (PPROM), hypertensive disorders or abruptio placentae, fetal growth retardation (FGR), or other ²³) and mode of delivery.

Infant characteristics considered were gestational age at delivery (in completed weeks' gestation), sex, small for gestational age (SGA) using the French intrauterine growth curves ²⁴, admission temperature (within 12 hours after birth), surfactant (0, 1 or 2 doses) for infants admitted to NICU and postnatal transfer (including repatriation transfers).

We also investigated three evidence-based practices which were recommended in the early 2010's and were identified as improving survival without severe neonatal morbidity in VPT infants ²⁵: any administration of antenatal corticosteroids before delivery; effective prevention of hypothermia defined as temperature on admission of 36°C or more; and surfactant used within two hours or early nasal continuous positive airway pressure (CPAP) for infants born before 28 WG for infants admitted to NICU.

This study was approved by the National Data Protection Authority (CNIL no.911009) and by the appropriate ethics committees (Consultative Committee on the Treatment of Data on Personal Health for Research Purposes - reference no. 10.626, Committee for the Protection of People Participating in Biomedical Research - reference CPP SC-2873).

Statistical analyses

Univariate analyses were performed to describe the population characteristics and evidence-based practices according to hospital volume, using Chi-squared tests. Statistical significance was set at a two-tailed test with $P < .05$. We used weighted percentages and gestational age adjustments in the multivariable analyses to account for differences in sampling times between gestational age groups.

Multivariate logistic regression analyses with population average models were used to analyze the association between hospital volume and the study outcomes taking into account clinical and healthcare factors known to affect outcomes and hospital volume. These factors were sex, gestational age, small for gestational age (<10th percentile) ²⁴, maternal age, infertility treatment, principal cause of prematurity, multiple or singleton pregnancy, parental socio-economic status and mother's country of birth. We used a generalized estimating equation (GEE) approach to take into consideration the clustering of births within hospitals ²⁶.

To check the robustness of the results, two sensitivity analyses were performed. First, for children aged between 24 and 25 weeks' gestation, there was no consensus about active management across French regions in 2011 ^{18,27}, and the decision to initiate resuscitation at birth varied greatly between hospitals. These children are considered to be on the edge of viability in France ^{28,29}. Therefore, we conducted analysis on a restricted population of 26-30 weeks for whom active resuscitation was commonly initiated in France ³⁰. Secondly, as mortality is higher in French overseas departments and territories ³¹, an analysis was conducted on only the newborns born in metropolitan France. Finally, because newborns were potentially transferred to another level III unit after birth, we performed a sensitivity analysis by excluding newborns hospitalized in more than one level III unit.

Survival at discharge was reported for all live births. In contrast, to account for dropouts and missing information, survival without severe neonatal morbidity at discharge and survival without neuromotor and sensory disability at 2 years corrected age was reported after multiple imputation. Among survivors, results are reported for both complete cases and all cases after multiple imputation. Missing data were imputed by chained equations using the SAS “MI” procedure ³². Imputation model variables included maternal, antenatal and neonatal characteristics (maternal age, parity, parental socioeconomic status, country of birth, infertility treatment, principal cause of prematurity, antenatal steroids, multiple pregnancy, caesarean section, SGA, gestational age, sex, Apgar score, surfactant, admission temperature), and outcomes (severe neonatal morbidities, cerebral palsy, neuromotor or sensory disabilities, and ASQ). For ASQ, missing domains were separately imputed to account for partially completed questionnaires and ASQ score was then estimated using the imputed domain specific data for infants without cerebral palsy, deafness, or blindness. Binary variables were imputed using logistic regression and socioeconomic data were imputed using multinomial models. We generated 50 independent imputed datasets with 30 iterations each. Estimates were pooled according to Rubin’s rule ³³. Further details are available in Table I (available at www.jpeds.com). All analyses were carried out with SAS v9.4 software.

Results

Admissions per year were <55 (Quartile 1, Q1), 55-79 (Q2), 80-109 (Q3) and > 110 (Q4), with a range of 14 to 174 very preterm babies admitted per hospital. Hospital characteristics are presented in Table 2 (available at www.jpeds.com). Of the high-volume hospitals, 87% were part of a University system and 80% performed neonatal surgery.

In total, 2447 infants were born between 24 and 30 weeks gestation in 66 level III hospitals (Figure 1; available at www.jpeds.com). Table 3 and Table 4 provide maternal and neonatal characteristics according to hospital volume. Q4 hospitals had higher proportions of women born outside France and of women from a higher socioeconomic status.

Only 10% of newborns were admitted to low volume units (Q1). In this group, significantly fewer women received fertility treatment or were transferred before delivery. Moreover, compared with infants born in Q4 hospitals, infants born in Q1 hospitals less frequently received antenatal steroids or surfactant, and presented more frequently with hypothermia. The principle cause of preterm delivery, gestational age, SGA and sex did not differ according to hospital volume.

The proportion of infants receiving all three evidence-based interventions increased significantly with hospital volume, from 49.8% in Q1 hospitals to 64.0% in Q4 hospitals. The proportion of infants receiving surfactant therapy or early nasal CPAP did not significantly differ according to hospital volume (Figure 2).

Survival at discharge was lower in Q1 hospitals (adjusted odds ratio (aOR) 0.56, 95% CI 0.33-0.91, Table 5). The percentages of severe neonatal morbidity were significantly higher in the two top quartiles (Table 6; available at www.jpeds.com). Survival without severe neonatal morbidity did not differ with hospital volume (Table 5).

A total of 2116 infants were discharged home, 13 died after discharge and 104 children did not participate in follow-up. In all, 1999 children were included in follow-up; the medical questionnaire for 2 years corrected age was completed for 1764 children (83.4%) and the ASQ at 22-26 months corrected age was available for 1232 (58.6%) (Figure 1). Data were more frequently missing from children born to families with low socioeconomic status (Table 1).

Survival without neuromotor or sensory disabilities at two years was lower in Q1, Q2, Q3 hospitals vs. Q4 hospitals, but the aOR was only significantly lower in Q1 hospitals (aOR 0.60, 95% CI 0.38-0.95) (Table 5). Results from the sensitivity analyses were similar (Table 7; available at www.jpeds.com). Our findings were also similar when we excluded newborns (n=49) who were hospitalized in several level III units (Data not shown). Among surviving infants, we found no significant difference in the incidence of neuromotor or sensory disabilities or ASQ below threshold according to hospital volume (Table 8; available at www.jpeds.com).

Discussion

In this population-based cohort study, we found that infants born between 24 and 30 weeks gestation and admitted to low volume neonatal units had consistently lower aOR for survival without neuromotor or sensory disabilities at 2 years corrected age vs. high volume units. Neuromotor and sensory disabilities and low ASQ score did not vary with hospital volume.

The EPIPAGE-2 study is based on a large national prospective cohort. Numerous maternal and neonatal characteristics were collected, thus increasing the robustness of the adjustments. A robust system of verification was used involving study statisticians and local investigators with access to original care notes. We used the volume of admission of VPT newborns in NICU as the exposure variable because this variable is a more relevant and accurate indicator of medical activity in the management of preterm infants than other indicators such as obstetric volume. Our exposure variable was based on reliable data from the national hospital discharge database³⁴. A GEE approach was used to take into consideration the clustering of births within hospitals, and sensitivity analyses were performed to account for possible variations in management of VPT newborns between perinatal networks. Only live births in level III

hospitals were included; this selection limits the generalization of our results for all neonates born between 24 and 30 weeks, but it has the advantage of analyzing relatively similar services (staff and equipment) and relatively similar newborns not transferred after birth.

The main limitation of our study is the follow-up rate at two years, which was lower than in other recent cohort studies on extremely preterm births³⁵⁻³⁷, but these studies included fewer infants. The proportion of children lost to follow-up was higher in families with low socioeconomic status¹⁹ and in hospitals with low neonatal activity, but the neonatal characteristics of these children were similar to those followed-up. Multiple imputation was used to account for missing data.

The quality of care received by newborns during their successive neonatal hospitalizations until discharge may have affected the relationship between hospital volume in the initial hospital and outcomes even though there were fewer postnatal transfers among children born in low volume hospitals.

If volume is an indicator of the experience and organization of a service, it would be better to use the volume before inclusion (2010), but the collection of gestational age in the national hospital discharge database only became mandatory in 2011. NICU volume may be a surrogate for other hospital characteristics or case-mix that contribute to the risk of disabilities. To limit this effect, children with lethal malformations were excluded, and numerous risk factors were introduced in the models.

In our study, a large proportion of NICUs had a high number of admissions, making it difficult to distinguish effects between NICUs with over 55 admissions of VPT newborns per year. In addition, our sample was not large enough to detect moderate differences in the intermediate groups, which might have clinical significance. We were also unable to identify an

admission threshold in the lowest-volume NICUs for which survival without disability would be significantly lower. One previous study ⁷ used modeling techniques to select the thresholds for investigation, but this required a much larger sample size, and they did not present data on longer-term neurodevelopment.

Another limitation is the lack of data on maternal distance to the closest level III maternity unit. However, low-volume NICUs (Q1) are not always located in isolated areas; for example, only 3 out of the 40 perinatal networks existing in 2011 had a low volume NICU as the sole NICU in the network. In addition, outborn infants are most affected by distance ^{38, 39}, but our study did not include this population.

Previous studies on the effect of volume on neonatal care have mainly used retrospective cohorts ^{7,11,12}, which had the advantage of large populations, but only studied in-hospital mortality and severe neonatal morbidity. These studies found that hospitalization in the top volume quartile was associated with a decreased risk of death. However, improved survival can potentially lead to an increase in the number of vulnerable infants developing neonatal and long-term complications. We found a trend toward increased severe neonatal morbidity in our study, and two other studies have shown an increased risk of BPD and ROP treatment in large units ^{11,12}. Our results suggest, however, that neuromotor and sensory disabilities at 2 years and psychomotor development did not differ with neonatal unit volume.

To understand the differences in survival between hospitals, factors such as number of beds, university status and level of care have been explored, but none were shown to be associated with survival ^{9,10}. On the contrary, the association with NICU volume found in several countries shows the importance of this factor. A high volume of activity may be associated with other beneficial factors such as better coordination of obstetric-pediatric care, more experienced

caregiving staff, or better implementation of clinical guidelines, as our study suggests. The three clinical practices investigated in our study can be considered indirect markers of the quality of perinatal care because they have been strongly recommended since 2011 and involve both obstetrical (antenatal steroids) and neonatal practices (prevention of hypothermia and surfactant or early nasal CPAP). The large variability of clinical practices across countries^{40,41} suggests that other clinical practices should be considered in order to understand which practices have a major impact on infant health. Evidence-based practices should be encouraged through appropriate training and evaluation in particular in the smallest volume hospitals. Morbidity and mortality reviews and the clinical pathway, as described by Rotter et al, are methods for evaluating and improving practices and could help obstetrical and neonatal teams improve the management of VPT infants.⁴²

Our results suggest that volume has an impact on survival without neuromotor and sensory disabilities mainly in the lowest activity units. This raises the question of whether it is necessary to establish volume thresholds for the admission of very preterm births in neonatal units, as recommended or enforced for level III units since 2003 in Belgium, Germany (50 VLBW), the Netherlands (200 total admissions)⁴³ and in the United Kingdom (100 VLBW)⁴⁴. However, closing the lowest activity NICUs could impede or delay maternal transfers, thereby increasing the number of infants born outside level III hospitals³⁹. Policy decisions regarding perinatal regionalization must therefore weigh the respective impact of NICU volume and the geographic access to these units, as has been done in limited-access zones⁴⁵.

In conclusion, our study suggests that the higher survival rate in the highest volume neonatal units was not followed by a higher risk of disability at two years. Further studies should focus on

why survival at discharge for very preterm infants admitted to small-volume neonatal units is significantly lower. Our results add new information to the ongoing debate on the optimal regionalization of perinatal care.
