Abstract

To estimate the genetic diversity and population structure for a better understanding of the spread of *Botrytis cinerea*, we genotyped with nine microsatellite markers 174 isolates collected from four greenhouses during three growing seasons in the region of Bejaia. Four of these isolates were detected as *B. pseudocinerea* according to the allele size at locus Bc6. For all other isolates further studied, all loci were polymorphic , with the mean number of alleles per locus ranging from 2.77 to 5.22. Considerable genetic variability was detected in all sub-populations (D*>0.87; Hnb>0.40). Based on the standardized index of association analysis, significant but low level of clonality occured, not excluding the possibility of recombination. (r_D=0.07, *P*<0.001). A total of 109 haplotypes were characterized among the isolates, few of which were shared between sub-populations. This, together with moderate genetic differentiation among sub-populations according to the geographic origin (0.080<F_{ST}<0.167), suggested a low level of inoculum exchange among greenhouses and little carryover of inoculum from one sampling season to the next. The importance of genetic structure of *B. cinerea* populations is discussed and should be taken into consideration for the management of gray mold.

Key words: Microsatellite makers / Gray mold / Genetic diversity/ Inoculum exchange

Introduction

Dispersion is a key process in the dynamics and evolution of natural populations. In addition to its primary role in the colonization process, dispersion also affects the process of adaptation of organisms. In plant pathogens, a better understanding of the dispersion process thus appears to be a major issue for better control. The pace at which microbes spread to new niches is a critical determinant of the emergence or re-emergence of infectious diseases in plants (Anderson et al. 2004). Plant pathogens are dispersed by contact, wind, water, animal vectors (e.g. insects and birds) and by humans through seed and infected plant material (Nagarajan and Singh 1990). Dispersal can occur over a distance from a few centimeters or less between roots in soil to hundreds of kilometers between susceptible crops. The transport of a small number of pathogenic spores can result in the eventual infection of entire fields (Mims and Mims 2004; Viljanen-Rollinson et al. 2007).

For many fungal plant pathogens, long-distance dispersal is an important strategy enabling them to colonize new areas or to survive between different seasons (Brown and Hovmøller 2002; Isard et al. 2005).

Local spread of inoculum is also of interest for day-to-day disease management and much effort has been dedicated to studying short-distance gradients of dispersion for various plant pathogenic fungi, including *B. cinerea* (Agrios 2005; Allard and Soubeyrand 2012; Mfegue et al. 2012; Johnson and Powelson 1983). Gradients of dispersion are considered to be influenced by many factors, including the type of cropping system (Qandah and Del Rio Mendoza 2012). Greenhouses, for example, are often regarded as quasi-closed systems, which generate short distance dispersal (Campen and Kempkes 2009). However, depending on the season and the type of greenhouse, substantial exchange of air can occur between the inside of a greenhouse and its outside environment (Boulard et al. 1997; Fatnassi et al. 2009), which could thus result in concomitant exchange of airborne inoculum.

While direct observation of the movements of airborne inoculum is a difficult experimental task, other approaches have been used to study the spread of inoculum within a greenhouse and possible exchanges with the outside environment. This is the case for *Botrytis cinerea*, a fungus known for its capacity to produce massive amounts of anemophilic spores on diseased plant tissue, and considered as a key pathogen on many greenhouse crops (Dik and Wubben 2004). Using selenate-resistant mutants, Korolev *et al.* (2006) clearly demonstrated the exchange of airborne inoculum in both directions (in- and outbound) between a glasshouse and its close environment. Modelling approaches have also been developed for the quantification of such exchanges (Leyronas and Nicot 2013; Leyronas et al. 2011).

In contrast, little is known about the spread of inoculum beyond the vicinity of a greenhouse despite its potential impact on disease management practices, possibly because of experimental difficulties. Nevertheless, molecular typing of isolates and tools of population genetics offer the possibility of an indirect approach to this subject through the comparison of distant sub-populations of the pathogen. In the case of *B. cinerea*, microsatellite markers are available (Fournier et al. 2002) and previous studies have shown a high level of diversity among isolates of this fungus on a variety of crops, allowing for comparison of population structures (Fournier and Giraud 2008; Isenegger et al. 2008a; Karchani-Balma et al. 2008). While populations of *B. cinerea* have been well characterized in various regions of the world (Fekete et al. 2012; Fournier and Giraud 2008; Decognet et al. 2009; Esterio et al. 2011; Ma and Michailides 2005; Mirzaei et al. 2009), information is scant for northern African countries (Karchani-Balma et al. 2008) and lacking for Algeria.

The main objectives of the present study were thus to establish a first detailed record of the genetic characteristics of the *B. cinerea* population in a vegetable growing area of Northern Algeria. A second objective was to identify traits that are compatible with the

80   hypothesis that exchange of inoculum occurred between farms. For this, isolates were

81   collected from diseased plants in greenhouses of the Bejaia region during three growing

82   seasons, and their genetic features were examined to test the hypothesis of a geographical

83   effect on the structure of the population.

84

85   **Materials and methods**

86   **Fungal sampling and isolation**

87   A total of 264 *B. cinerea* isolates were collected from commercial tomato

88   greenhouses in May-June of 2007, 2008, and 2010, in the Bejaia region of Algeria

89   (Fig. 1, Table 1). Access to one of the sampling sites (greenhouse in Souk El

90   Tenine) was not possible after 2007. Using sterile cotton swabs, isolates were taken from

91   diseased plant organs (fruits, leaves, flowers and stems) showing abundant sporulation,

92   brought back to the laboratory and stored at –20°C until use for isolate purification and single

93   spore isolation as described by Leyronas et al. (2012).

94   To produce mycelial tissue for DNA extraction, the single spore isolates were

95   cultured on malt extract agar medium at 25°C in the dark. After 10-14 days of incubation,

96   mycelia and conidia were collected by adding 1 ml of sterile distilled water in the Petri

97   plates, and by scraping the surface of the colony with a sterile cotton pad. The fungal

98   material was then lyophilized and stored at –20°C until used for DNA extraction.

99   **DNA extraction**

100   The DNA of all field isolates of *B. cinerea* was extracted from 15 mg aliquots

101 of lyophilized fungal material in 96-well plates, using a DNeasy Plant extraction maxi Kit

102 (Qiagen®). DNA quality and quantity were assessed using agarose gel (1%)

103 electrophoresis. The plates containing DNA were then stored at –20°C until used for

104 microsatellite amplification.

Microsatellite amplification and size analysis

Amplification reactions for the nine microsatellite loci described by Fournier et al. (2002) were carried out using a QIAGEN® Amplification Multiplex PCR kit. Some of the primers had the same annealing temperature, which allowed the amplifications to be multiplexed. The reaction mixture consisted of 552 µl of PCR Master mix (containing DNA polymerase, MgCl Multiplex PCR buffer and triphosphate-deoxyribonucleotides), 242µl of MilliQ water and 22µl of each multiplexed primer. Each well of a PCR plate contained 8 µl of reaction mixture and 2 µl of DNA from a *Botrytis* isolate.

The amplifications were carried out using an Eppendorf thermocycler. They entailed an initial preheat for 15 min at 95°C, followed by 25-40 cycles comprising 0.5 min of denaturation at 94°C, 1.5 min of annealing at 50°C (for the microsatellite loci Bc1, Bc3, Bc6, Bc9), 53°C (for Bc2 and Bc5) or 59°C (for Bc4, Bc7, Bc10) and 1 min of extension at 72°C. Amplifications were ended by a final extension step of 30 min at 60°C. In order to verify that the amplification occurred, sub-samples were then taken from each well and deposited on 1% agarose gels for electrophoresis.

The amplification products were stored at -20°C until used for assessing the sizes of the microsatellites. After a denaturation phase at 94°C for 3 min and addition of size markers, amplification products were scanned with an ABI 3730 xl DNA sequencer. Data were analyzed with GeneMapper software (Applied Biosystem). Based on the sizes of the 9 microsatellite markers, a haplotypic profile could be assigned to each isolate, defining multilocus genotypes (MLG). Genotyping was repeated for some (but not all) of the isolates to confirm the results. Isolates belonging to subspecies *B. pseudocinerea* are morphologically identical to those of *B. cinerea*, but they can be identified on the basis of the allele size at locus Bc6 (Walker et al. 2011).

129 **Population genetics analysis** The analysis was carried out only for isolates of *B. cinerea*

130 (excluding *B. pseudocinerea*) whose complete 9-microsatellite haplotypic profile could be

131 obtained.

132   The software Genetix 4.05 (Belkhir et al. 1996) was used to compute an index of

133 unbiased allelic diversity (Hnb), the mean number of alleles per locus (based on allele

134 frequencies) and allelic richness over all loci in the total sample and in each sub-population

135 collected in the four greenhouses cited previously. Intra-population diversity was

136 characterized by computing diversity indices using Genclone software (version 2.0). We used

137 the Simpson diversity index (D*), an equitability index (ED*) and the index of genotypic

138 richness (R). The D* index measures the probability that two randomly selected individuals in

139 a population have different MLGs (Arnaud-Haond et al. 2007). The ED* index is equal to 1

140 when all MLGs represented in a population have the same abundance (equitable distribution

141 of clones) (Arnaud-Haond et al. 2007). Finally, we used the R index of genotypic richness,

142 which varies from 0 when all isolates in a sample possess the same genotype, to 1, when all

143 isolates possess a different genotype (Dorken and Eckert 2001).

144   In order to test for genetic recombination, the standardized index of association (r_D) was

145 calculated using Multilocus 1.3b (Agapow and Burt 2001). The r_D index is a measure of the

146 multilocus linkage disequilibrium (Brown et al. 1980; Haubold et al. 1998), which gives

147 information on whether two different individuals sharing the same allele at one locus are more

148 likely to share an allele at another locus. For each pair of isolates, the number of loci with

149 respect to which they differ is calculated, and the variance of this number is compared with

150 that expected if there is no linkage disequilibrium. The r_D index is equal to zero if there is no

151 linkage disequilibrium, and it increases as linkage disequilibrium increases. The null

152 hypothesis of complete panmixia ($r_D = 0$) was tested with the procedure implemented in the

153 software, by comparing the observed data set to 1000 randomized data sets in which infinite

154 recombination has been imposed by randomly shuffling the alleles among individuals,

155 independently for each locus.

Genetic differentiation between sub-populations

157   Estimation of genetic differentiation by pairwise comparison between the sub-

158 populations collected at different locations in a given season was performed using the

159 software ARLEQUIN 3.0 (Excoffier et al. 2005), without repeated MLGs, after 3024

160 permutations and progressive Bonferroni correction as described by Rice (1989). According

161 to Wright (1978), the genetic differentiation between two populations is low when

162 $0 < F_{ST} \leq 0.05$, moderate when $0.05 < F_{ST} \leq 0.15$, substantial when $0.15 < F_{ST} \leq 0.25$ and very high

163 when $F_{ST} > 0.25$.

Results

Distinction between *B. cinerea* and *B. pseudocinerea*

166   After isolation, single-spore purification, DNA extraction and genotyping of the 264

167 isolates, complete genotypic profiles with the nine microsatellites were obtained for only 174

168 isolates. No variation of the microsatellite sizes was found after genotyping repetitions of

169 some isolates. Four of them, collected in Tichy in 2007 and 2008, were characterized as *B.*

170 *pseudocinerea* and excluded from further genetic analysis. We had thus 170 fully genotyped

171 isolates of *B. cinerea*, distributed in nine groups of approximately 20 isolates per sampling

172 site and per year (Table 2; one exception in Tichy in 2007 with only 5 isolates). Each of these

173 groups will be referred to as a "sub-population" in the rest of this paper.

Global genetic diversity

175   A total of 109 multilocus genotypes (MLG) were distinguished among the 170 isolates

176 of *B. cinerea* and the mean number of alleles per locus was 8.22 (Table 2). The overall level

177 of genetic diversity in the total population was high, as shown by an unbiased genetic

178 diversity (Hnb) of 0.57, an index of genotypic diversity (D*) of 0.98 and a Richness index (R)

179   of 0.64. The high index of equitability (ED*= 0.90) indicated an equitable distribution of

180   clonal haplotypes between the nine sub-populations. Finally, the estimate of linkage

181   disequilibrium was significant but very low (r_D=0.07), suggesting the occurence of limited

182   genetic recombination (Table 2). Although the results obtained for the total sample were

183   interesting in our study, other repetitions in the time for the site of Souk-El-Tenine must be

184   undertaken to confirm these results.

185   **Genetic diversity among sub-populations**

186   Separate examination of the nine sub-populations confirmed the overall high level of

187   allelic diversity, with an Hnb index ranging from 0.40 to 0.68 (Table 2). This diversity

188   appeared higher in 2010 than in other years. The average number of alleles per locus was 8.22

189   for the total sample and ranged from 2.77 to 5.22 within the nine sub-populations, suggesting

190   that several alleles were not shared among sub-populations. Haplotypic diversity was also

191   high, with a D* index higher than 0.90 in eight of the nine sub-populations. Significant but

192   low multilocus linkage disequilibrium (r_D) was observed in all sub-populations (Table 2; one

193   exception: Tichy 2007, for which only 5 isolates were available).

194   Among the 109 MLGs observed within the total sample, 88 were represented by a

195   single isolate and 21 were represented by at least two isolates (Fig. 2). Among those, twelve

196   were shared between sub-populations collected in different greenhouses and seasons (Table

197   3). One MLG was detected 17 times in the total sample and was shared between four sub-

198   populations. The number of shared MLG between greenhouses varies with the year.

199   Therefore, 3 MLGs were found in 2008, only 2 in 2010 and 1 MLG was found in 2007 (Table

200   3).

201   **Genetic differentiation between sampling sites**

202   Pairwise tests of genetic differentiation among sub-populations yielded generally low

203   to moderate F_{ST} values (Table 4). The highest values were obtained in 2007 between Tichy

204   (site C) and the two other coastal sites, showing significant genetic differentiation between

205   these sub-populations on that year. Moderate but significant differentiation was also observed

206   between Tichy and Baccaro (site B) in 2008. No significant differences were observed in

207   2010.

208   **Discussion**

209   This study provides the first data on genetic features of *B. cinerea* populations in

210   Algeria. It is also the first report of the detection of *B. pseudocinerea* in North Africa. This

211   species, detected at a frequency of 1.5 % among the 264 isolates collected in our study, was

212   also observed at low frequencies (varying between 0.5 and 15% according to the location and

213   the season) in other parts of the world, in sympatry with *B. cinerea* populations (Fekete et al.

214   2012; Fournier et al. 2005; Fournier et al. 2003; Martinez et al. 2005; Scagnelli et al. 2010,

215   Walker et al. 2011; Wissels 2012; Ma and Michailides 2005).

216   Among the isolates of *B. cinerea*, the high genetic diversity (both allelic and

217   haplotypic) observed in the present study indicates a highly heterogeneous population. Similar

218   situations have been described for populations collected from different hosts around the world

219   (Table 5). Such high levels of diversity could result from genetic recombination, as suggested

220   by the low value of the standardized index of association r_D found in the present work and in

221   several previous studies (Table 5). High levels of recombination have been reported for most

222   studies of *B. cinerea* populations, with the exception of a study in various field crops in

223   California (Ma and Michailides 2005). Recombination has been mostly attributed to sexual

224   reproduction, and could also be related to other mechanisms of variability known for *B.*

225   *cinerea* (Van Der Vlugt-Bergmans et al. 1993; Beever and Weeds 2004).

226   The overall level of clonality in the *B. cinerea* population, measured by the ratio of the

227   number of distinct MLGs present among the total number of isolates characterized in the

228   present study was 0.64. When considering the sub-populations of individual greenhouses, it

was consistently higher than 0.56. These numbers are overall similar to those reported for studies of *B. cinerea* in various crops and locations (Table 5). However, they contrast sharply with results of a study conducted in tomato greenhouses in experimental conditions (Decognet et al. 2009). In that study, the ratio of the number of distinct MLGs identified among the total number of characterized isolates was 0.70 among isolates sampled from the air spores before the development of the disease in the greenhouses. It decreased sharply to a value of 0.23 among isolates sampled from the air 15 days after the inoculation of plants with two known strains of *B. cinerea*, and decreased further to 0.03 among isolates collected from diseased plants 60 days after inoculation. Under the hypothesis that two isolates sharing an identical genotypic profile were clones, these authors concluded that abundant sporulation by the two introduced strains of *B. cinerea* resulted in a displacement of the initially present population (Decognet et al. 2009).

In the present study, we observed identical MLGs in different greenhouses during a given year (Table 3). This observation is compatible with the hypothesis that inoculum exchange may have occurred between greenhouses. This hypothesis is supported by the fact that genetic differentiation (Fst values) was not significant on a given year for greenhouses which shared MLGs (one exception in 2008 for Baccaro and Tichy; Table 4). The possibility of inoculum exchange between the greenhouses is also supported by meteorological data showing that prevailing winds in the Bejaia region are west-bound between April and September (Alkama et al. 2007; http://fr.windfinder.com/windstats/_windstatistic_bejaia_aeroport.htm), a period that covers the time when *Botrytis* epidemics occur in the tomato greenhouses of that region (Aissat et al. 2008). Considering the dominant wind direction during our study and the distance between the sampling sites, genotypic data are generally (but not systematically) in agreement with possible contribution of inoculum between greenhouses from the most eastern to the most western site of a given year.

254   Earlier studies have reported genotype flows between regions for *B. cinerea*

255   populations examined in chickpea fields in Bangladesh (Isenegger et al. 2008b) and for two

256   other species of *Botrytis* in field crops in the Netherlands (Staats 2007). In our study, the

257   small number of shared MLGs between sampling sites could be due to the fact that

258   greenhouses are somewhat confined environments, although some level of inoculum

259   exchange between the inside and outside of a greenhouse has previously been demonstrated

260   (Korolev *et al.* 2006). However, the occasional presence of shared MLGs in different

261   greenhouses of the Bejaia region could also result from their presence in multiple copies in

262   global air masses arriving to that region. A consideration of the trajectories of air masses

263   across the Mediterranean (Kushta et al. 2012; Khalfa et al. 2013; Lelieveld et al. 2007) makes

264   it impossible to exclude occasional influx of *B. cinerea* inoculum from more distant sources,

265   such as agricultural regions in southern France and Spain where *Botrytis* is known to be

266   abundant (Leyronas and Nicot 2013; Moyano et al. 2003). This hypothesis is further

267   supported by the detection in Bejaia of *B. pseudocinerea*, a new species formerly described in

268   France and considered to be migrating to other parts of the world (Isenegger et al. 2008b).

269   More conclusive evidence for direct exchange of inoculum among farms of the Bejaia region

270   would thus require additional information on short term evolution of the population structures

271   during a growing season, together with concomitant information on dominant haplotypes

272   present in distant potential sources of occasional inoculum. In the meantime, gray mold

273   management strategies in the Bejaia region should not rule out the possible exchange of

274   inoculum between farms and thus the spread of particularly aggressive strains or fungicide-

275   resistant strains.

[a] MLG: multilocus genotypes.

[b] Hnb: nonbiased genic diversity, calculated with repeated genotypes (standard deviations between brackets),

ND: undefined.

[c] D*: genotypic diversity index; E: equitability index; R: Richness index.

[d] r_D: standardized index of association.

Table 3. Frequency distribution of Multilocus Genotypes (MLG) detected in more than one greenhouse.

MLG	2007			2008			2010		
	Souk-el-Tenine	Baccaro	Tichy	Baccaro	Tichy	Merdjouamane	Baccaro	Tichy	Merdjouamane
H20		2		1	1		2		
H32		1		1					
H89				2			3		
H25								2	2
H30	7	1				8		1	
H55		2							
H65					1	2			
H80					1				1

H88				1		3			
H100			1		1		1		
H108							1	1	

Table 4. Genetic differentiation (F_{ST}) of *B. cinerea* sub-populations sampled from four sites in the Bejaia region of Algeria.

Season	Site A-Site B[a] (13 km)	Site A-Site C (23 km)	Site B-Site C (10 km)	Site B-Site D (20 km)	Site C-Site D (15 km)
2007	0,062[b]	<u>0,167</u>	<u>0,115</u>	ND[d]	ND
2008	ND	ND	<u>0,095</u>	0,058	-0,019
2010	ND	ND	0,011	0,016	0,050

[a] A: Souk-el-Tenine; B: Baccaro; C: Tichy; D: Merdjouamane. Numbers between brackets indicate the distance in km between two sampling sites.

[b] Pairwise F_{ST} were calculated following Weir and Cockerham, without repeated MLG. Underlined values are significantly different (*P* <0.01) after 3200 permutations and a Bonferroni correction.

[c] ND: not determined.

Table 5. Genetic diversity indices of *B. cinerea* populations characterized with microsatellite makers

Origin of study	Host plant	Number of microsatellites	Number of isolates	Number of MLGs	Number of MLG/Number of isolates	Hnb[a]	D*[b]	r_D[d]	Reference
Algeria	Tomato	9	170	109	0.64	0.57	0.98	0.07	Present study
France	Grapevine, bramble	8	184	180	0.98	0.75	0.75	-	Fournier et al. 2008
Tunisia	Grapevine, faba bean, tomato, strawberry	9	153	120	0.78	0.79	0.99	0.08	Karchani-Balma et al. 2008
Hungary	Strawberry, rape	5	79	32	0.40	0.66	0.91	0.08	Fekete et al. 2012
Bangladesh	Chickpea fields	9	146	69	0.47	0.25	0.54	-	Isenegger et al.2008
South Africa	Pear orchards	9	181	91	0.50	0.14	0.69	-	Wessels 2012
