20

21 **Abstract**

22 Aflatoxin B1 (AFB1) is a carcinogenic mycotoxin produced by *Aspergillii* of the section
23 *Flavi* that may contaminate food, in the field or during storage. Cassava represents an
24 important staple food in sub-saharian Africa. The analysis of aflatoxigenic fungi in 36
25 cassava samples obtained from producers in Benin indicated that 40% were
26 contaminated by *Aspergillii* of the section *Flavi*. Upon morphological and molecular
27 characterization of the 20 isolates, 16 belonged to *A. flavus*, 2 to *A. parvisclerotigenus* and
28 2 to *A. novoparasiticus*. This is the first time that this latter species is isolated from food.
29 Although most of these isolates were toxigenic on synthetic media, no AFB1
30 contamination was observed in these cassava samples. In order to determine the action
31 of cassava on AFB1 synthesis, a highly toxigenic strain of *A. flavus*, was inoculated onto
32 fresh cassava and despite a rapid development, no AFB1 was produced. The anti-
33 aflatoxin property was observed with cassava from different geographical origins and on
34 other aflatoxigenic strains of the section *Flavi*, but it was lost after heating, sun drying
35 and freezing.

36 Our data suggest that fresh cassava is safe regarding AFB1 contamination, however,
37 processing may alter its ability to block toxinogenesis leading to secondary
38 contamination.

1. Introduction

Mycotoxins are toxic secondary metabolites produced by fungi and are common contaminants of food and feed commodities worldwide. Over 400 mycotoxins are known today; due to their occurrence and toxicity, aflatoxins, fumonisins, ochratoxin, zearalenone and trichotecenes are usually considered as the most important for human health (Leslie et al., 2008).

The most toxic and dangerous mycotoxins are aflatoxins. Indeed, aflatoxin B1 (AFB1) is the most potent hepatic carcinogen known in mammals and has been classified by the International Agency for Cancer Research in the group I of molecules that are carcinogenic for both humans and animals (IARC, 1993). AFB1 also possesses immunosuppressive properties (Meissonnier et al., 2008) and is involved in growth impairment observed in children (Gong et al., 2004; Khlangwiset et al., 2011). Exposure to aflatoxins in sub-Saharan Africa is very frequent. In some areas, 99% of children tested have aflatoxins in their blood (Gong et al., 2002) and this high exposure contributes to appearance of chronic hepatomegaly in children (Gong et al. 2012). Contamination of food by very high levels of aflatoxins can lead to fatal consequences such as the reported death of 125 people in Kenya (Lewis et al., 2005; Probst et al., 2007). The contamination of food by AFB1 may therefore have important consequences for human health and more than 100 countries have established maximal tolerable limits for this molecule (FAO, 2003; EU, 2006).

In the tropical countries highly exposed to aflatoxin, cassava (*Manihot esculenta Crantz*) belongs to the short list of most consumed foodstuffs. It is ranked as the third most important food crop in tropical regions after rice and maize. Due to its high energetic value, it represents an important part of the diet of almost one billion people, mostly in sub-Saharan Africa. In Africa, cassava is mostly devoted to human food, livestock feedstuff, but it is also used as a raw material in various industries that produce flour, starch, adhesives, etc. As human food, cassava may be consumed as fresh roots usually as a snack, but also after being peeled, grated or soak in water to ferment and then processed into a wet mash (fufu) or varied dry products (gari, chips/crumbs/chunks, or milled into flour) (Akoroda, 2007). The conditions of production and storage of cassava and its traditional derivatives may be favorable to the contamination and development of molds (Westby and Twiddy, 1991). Generally such uncontrolled mold developments

71 may not only result in alterations in the organoleptic properties of the foodstuffs but
72 may also lead to the accumulation of toxic secondary metabolites.
73 Due to its nutritional and economic importance in many tropical countries, it is
74 necessary to assess the contamination of these foods by mycotoxins. Previous surveys
75 performed in order to evaluate fungal and mycotoxin contaminations showed that some
76 mycotoxins such as patulin, cyclopiazonic, ochratoxin A, zearalenone could be found in
77 cassava (Wareing et al., 2001). However, no trace of aflatoxins has been mentioned,
78 although the warm and humid climate that prevails in tropical areas can promote the
79 development of aflatoxin-producing *Aspergillus* species (Muzanila et al, 2000; Jimoh and
80 Kolapo, 2008). Recently, we did a preliminary survey on cassava chips sold in Beninese
81 markets and found no aflatoxin contamination of cassava chips, despite a high presence
82 of *A. flavus* spores (Gnonlonfin et al., 2012).
83 Within this context, the objective of this current study was to understand the absence of
84 AFB1 in cassava products. Consequently, we firstly did a small survey to analyze fungal
85 flora and aflatoxins in cassava chip samples taken directly from producers in order to
86 evaluate the fungal contamination at this critical point in the food chain. We then
87 characterized the isolates of *Aspergillus* of the section *Flavi*, isolated during this survey
88 and the previous one, regarding their toxigenic potential. Finally, we investigated the
89 action of cassava on AFB1 synthesis and demonstrated that fresh cassava was able to
90 block AFB1 synthesis by toxigenic strains of *A. flavus*.
91

92 **2. Material and methods**

93

94 **2.1** Chemicals and reagents

95

96 All reagents including solvents were purchased from Fisher Scientific (Fontenay sous
97 Bois, France) and were of analytical grade. Aflatoxin B1 (AFB1), aflatoxin G1 (AFG1),
98 scopoletin and ergosterol standards were purchased from Sigma-Aldrich (Saint-Quentin
99 Fallavier, France). AFB1 and scopoletin were dissolved in methanol and ergosterol in
100 ethanol. Taq DNA polymerase used for molecular identification was purchased from
101 Invitrogen (Carlsbad, CA, USA). Agarose gel and primers used for gene determination
102 were purchased from Eurobio (Courtaboeuf, France).

103

104 **2.2** Cassava samples

105

106 For the survey, thirty six samples of cassava of about 1kg each were purchased from
107 local producers in the north of Benin during the dry season (December 2010) (Figure 1).
108 Samples were randomly chosen and checked for the absence of macroscopically visible
109 alteration or dryness.
110 For the experiments on *Aspergillus* development and toxinogenesis, two varieties of
111 cassava were used. The first one, named *Logoguesse Kotorou* in Bariba dialect was
112 grown in the north of Benin. The second variety, grown in Costa Rica, was purchased on
113 the market in Toulouse, France. These roots were protected from contamination and
114 alteration by a thin pellicle of wax.
115 These two varieties were intended for human consumption and corresponded to sweet
116 varieties with concentrations of cyanogenic compounds below 50 mg/Kg as evaluated
117 according to Essers et al. (1993).

118

119 **2.3** Isolation and Identification of fungi

120

121 *2.3.1 Origin*
122 Fungal analysis of cassava samples was done according to Gnolongin et al. (2012). In
123 brief, 1 ml of decimal dilutions were plated on Petri dishes containing dichloran glycerol
124 agar (DG18). Petri dishes were incubated at 25°C in alternating 12h periods of

125 fluorescence light and dark for 5 days. Colony were isolated by several plating out and
126 further identified as described below.
127 Twelve isolates coming from a survey done in 2009-2010 on cassava chips collected in
128 markets in Benin were added to the study (Gnonlonfin et al., 2012). Other strains of
129 *Aspergillus* of the section *Flavi* used in this study were obtained from the Agricultural
130 Reseach Service collection (NRRL) and CBS-KNAW Fungal Biodiversity Centre collection
131 (CBS): *A. flavus* NRRL 1957, *A. parasiticus* NRRL 5862, *A. parasiticus* NRRL 4123, *A.*
132 *tamarii* NRRL 20818, *A. bombycis* NRRL 26010, *A. pseudatomarii* NRRL 25517,
133 *Aspergillus parvisclerotigenus* CBS 121.62, *Aspergillus minisclerotigenes* NRRL 29000,
134 *Aspergillus minisclerotigenes* CBS117635.
135

136 *2.3.2 Morphological and molecular identification*

137 The 32 strains isolated from cassava were cultivated on Potato Dextrose Agar (PDA) (24
138 g/l potato-dextrose broth, 15% (w/v) technical agar (Becton, Dickinson and Co.,
139 Franklin Lakes, NJ, USA)) at 25°C for seven days. They were identified as *Aspergillus*
140 section *Flavi* isolates by both macroscopic and microscopic examination according to
141 Pitt and Hocking (2009) and Varga et al. (2011).
142 Identification of *Aspergillus flavus* isolates was also performed by PCR amplification of
143 the *cypA*/*norB* region as described in Probst et al. (2012). The culture conditions and
144 genomic DNA isolation were described by El Mahgubi et al. (2013). PCR reactions were
145 carried out in a GenAmp PCR 2700 thermocycler (Applied Biosystems, Forster City, CA,
146 USA). This identification was completed for 10 randomly selected isolates which showed
147 0.3 or 0.9 kb fragments by internal transcribed spacers (ITS) rRNA and 5.8S rRNA gene
148 amplification and sequencing. For the other isolates displaying no gap, added to ITS, the
149 molecular identification was performed by calmodulin, beta-tubulin or acetamidase
150 (*Amds12*) and o-methyltransferase (*Omt12*) genes amplification and sequencing.
151 Primers used in this study are listed in Table 1. For ITS amplification, PCR conditions
152 were those described by White et al. (1990). Beta-tubulin, calmodulin were amplified
153 under conditions previously described by Peterson (2008) whereas (*Amds12*) and o-
154 methyltransferase (*Omt12*) genes were amplified according to Geiser et al. (1998).
155 PCR products were purified with GenElute PCR clean–up kit (Sigma-Aldrich) and
156 sequenced by the dye terminator technology on an ABI3130XL sequencer (Applied
157 Biosystems). PCR products were sequenced in both directions.

158 Nucleotide sequence accession numbers for internal transcribed spacers (ITS) rRNA and
159 5.8S rRNA, beta-tubulin, calmodulin, acetamidase and O-methyltransferase of tested
160 isolates are reported to Table 2.

161

162 *2.3.3 Analysis of toxin pathway genes*

163 The toxigenic status of the *A. flavus* isolates was determined by analyzing the presence
164 of six genes involved in the aflatoxin biosynthesis pathway: *AflD* (*Nor-1*), *AflO* (*OmtB*),
165 *AflP* (*OmtA*), *AflQ* (*OrdA*), *AflR*, and *AflS*. The primers used were designed using the
166 sequences of the *A. flavus* strain NRRL 3357 deposited in GenBank and are reported in
167 Table 1. The PCR amplification was carried out in 50 µL reaction mixture (5 µl of Taq
168 polymerase buffer 10X, 1.5 µL of 50 mM $MgCl_2$, 1 µL of 10 mM dNTP (Promega, Madison,
169 WI, USA), 1.5 µM of each primer, 1.5 units of Taq DNA polymerase (Invitrogen, Carlsbad,
170 CA, USA), 5µl of genomic DNA (100 ng/µl), and 31 µl of pure water (Laboratoire
171 Aguettant, Lyon, France)). Reaction conditions were: 94◦C for 5 min, 40 cycles (1 min at
172 94◦C, 1 min at 58◦C, and 1 min at 72◦C) followed by 10 min at 72◦C. The amplified
173 products were examined by 1.2% w/v agarose gel electrophoresis.

174

175 **2.4** Aflatoxin B1 quantification

176

177 *2.4.1 In cassava chip samples*

178 AFB1 quantification in cassava chip samples was done on site according to the method
179 developed and validated by Gnonlonfin et al. (2010). Briefly, each sample (10 g) was
180 extracted with 1 g of sodium chloride and 25 mL of extraction solution [methanol/water
181 (80/20, v/v)] and purified on an Aflatest®immunoaffinity column (VICAM, Watertown,
182 MA, USA). The extract was dried under nitrogen gas at 60°C, dissolved in 200 µL of
183 methanol and analyzed by HPLC with a post-column derivatization using a
184 photochemical reactor for enhanced detection (PHRED). The limit of detection (LOD) of
185 the method was 0.1 µg/kg.

186

187 *2.4.2 In culture medium*

188 AFB1 production by *A. flavus* strains was determined after culture on PDA for 7 days at
189 25°C. Toxins were extracted from culture medium by mechanical agitation with 70 ml of
190 chloroform. The organic phase was evaporated in a rotary evaporator at 50°C. The

191 residue was taken up in 400 µl of methanol, and this suspension was filtered-through a
192 0.45 mm pore-size filter before analysis.
193 The mycotoxin was quantified by high performance liquid chromatography with
194 photodiode array detector (Thermo-Finnigan Suveyor HPLC-PDA system,
195 ThermoElectron Corporation, Whaltham, MA, USA). The liquid chromatography
196 separation was performed using a 150 mm x 2.00 mm Luna 5 µm C18 column
197 (Phenomenex, Torrance, CA, USA). HPLC was done with a linear gradient elution using
198 33 mM acetic acid (solvent A) and acetonitrile (solvent B) with a flow rate of 200 µl/min.
199 The compounds were eluted starting from 80% of solvent A for 5 min, followed by a
200 50% solvent B step, then a linear gradient up to 90% solvent B within 5 min. After
201 isocratic elution for 5 min, the gradient was decreased to its initial value within 2 min,
202 and maintained at it for the last 5 min.
203 Calibration curves for AFB1 were constructed using standard solutions in methanol
204 (from 0.1 to 100 µg/ml) at 365nm. The LOD was 2 ng/ml.
205
206 **2.5** *A. flavus* growth and toxinogenesis on cassava
207
208 *2.5.1 Culture conditions*
209 *Inoculum preparation*
210 Strains were cultured on PDA at 25°C in the dark for 7 days. After this period, the plates
211 were washed with 10 ml of 0.05% Tween and a spore suspension was harvested and
212 adjusted to 10^5 spores/ml after counting in a Malassez cell.
213 *Culture on cassava*
214 Before inoculation, the water activity of cassava was measured with an HC2-AW device
215 (Rotronik AG, Basserdorf, Switzerland) and adjusted to 0.98 by addition of the required
216 quantity of sterile water.
217 After peeling, cassava was cut into thin slices and inoculated immediately (fresh) or
218 after heat treatment (120°C for 20 min), freezing (-20°C for 2 months) or drying. For this
219 later treatment, cassava chips were processed as previously described (Gnonlonfin et al.,
220 2010). Everyday, the evolution of the water content was followed according to AOAC
221 934.01 (AOAC, 2000) and 200 g of cassava were used and inoculated as follow.

Fifteen grams of fresh or treated cassava were inoculated with 100 µl of a spore suspension (10^4 spores) and incubated at 25°C for 3 and 6 days in dark and high humidity conditions. Each experiment was done in triplicate.

2.5.2 Fungal development measurement

Conidia formation:

Spore numbers were determined after grinding cultures in phosphate buffer [(0.1M, pH7.4); 50 ml for 15 g cassava]. Ten-fold dilutions were prepared with tween 0.05% and the numeration of spores was done both by counting in a Malassez cell and by plating dilutions on malt agar and determining Colony Forming Units per gram (CFU/g) after 5 days at 25°C.

Ergosterol concentration

Ergosterol measurement was done according to Bailly et al. (1999). In brief, after saponification in methanol, ethanol, KOH and pyrogallol and extraction with petroleum ether, ergosterol was quantified by fluorodensitometry with a Shimadzu CS930 densitometer (Shimadzu, Kyoto, Japan) after separation of the extracts by thin layer chromatography on silica plates (Macherey-Nagel, Düren, Germany) in toluene-acetonitrile (70:30). Quantification was done by comparison with known amounts of standard spotted on the same plate.

2.5.3 Aflatoxin B1 measurement in cassava

The aflatoxin B1 was extracted from cassava with chloroform (50 mg/ml) and filtered-through a phase separator PS Whatman filter (GE Healthcare Biosciences, Pittsburgh, PA, USA). The extract was evaporated to dryness in a TurboVap Lv Evaporator (Zymark, Hopkinton, MA, USA) under N_2 atmosphere. Dry extracts were re-suspended and analyzed by HPLC-PDA as described above.

For spiking experiments, pure AFB1 was added on fresh or autoclaved cassava (5 ng/g cassava). Extraction and quantification of AFB1 was then done as described above.

2.6 Statistical analysis

253 Differences for ergosterol production and sporulation were evaluated for statistical
254 significance using an analysis of variance (two-way ANOVA). $P \leq 0.05$ was required for
255 significance.

256

257 # 3. Results

258

259 ## **3.1** Contamination of cassava chips with *Aspergillus* section *Flavi*

260

261 A survey was done to evaluate contamination with *Aspergilli* and the presence of AFB1
262 on 36 samples randomly collected from producers located in the North of Benin (Figure
263 1).

264

265 ### *3.1.1 Morphological and molecular characterization of fungal isolates*

266 Identification of fungal isolates from cassava samples was firstly done by morphologic
267 examination after growth on PDA medium. Nearly forty percent of samples collected
268 (38.9%) were found to be contaminated with strains that were morphologically
269 identified as *Aspergillus* of the section *Flavi* and a total of 20 different strains were
270 isolated, two samples being contaminated with 2 different strains. The presence of
271 sclerotes was observed in half of the strains.
272 Identification of these isolates to the species level was performed using molecular
273 methodologies. Twelve additional isolates previously isolated form marketed cassava
274 cheaps (Gnolonfin et al., 2012) were also submitted to such identification. As a first step,
275 identification of these isolates to the species level was performed by the determination
276 of the presence of a gap in *cypA*/*norB* region. The amplification of *cypA*/*norB* of 28
277 isolates revealed 0.9 or 1.5 kb deletion. Among the 32 isolates , 18 displayed 0.9 kb gap
278 and 10 displayed a 1.5 kb deletion (Table 3). The presence of these deletions strongly
279 suggested that the isolates belonged to *Aspergillus flavus* species. Indeed, the
280 cytochrome P450 monooxygenase encoded by *cypA* is required for aflatoxins G_1 and G_2
281 production and the partial deletions of *cypA* explain that *A. flavus* lacks capacity to
282 synthetize aflatoxins G (Ehrlich et al., 2004). Molecular identification based on ITS

283 sequences was also performed on 10 strains randomly selected from these isolates. This
284 confirmed that all belonged to *A. flavus* species (Table 2).
285 The amplification of *cypA*/*norB* region (1.8 kb) of the 4 remaining isolates (AFc31,
286 AFc32, AFc35 and AFc36) revealed an absence of gap. For these isolates, the alignment
287 of *cypA*/*norB* region sequences (KC990464-KC990468) to the full length sequence of
288 *Aspergillus parasiticus* NRRL 5862 (SRRC143) strain suggested that they could be able to
289 produce aflatoxins G.
290 For AFc31 and AFc32 isolates, the sequences obtained after ITS sequencing matched
291 100% with those of *A. novoparasiticus* species. In order to confirm that these isolates
292 belong to *A. novoparasiticus*, fragments of *AmdS12* and *Omt12* genes were amplified and
293 sequenced. The obtained sequences (Table 2) matched 100% with the *A. novoparasiticus*
294 sequences previously deposited in GenBank (Gonçalves et al., 2011).
295 AFc35 and AFc36 share identical ITS sequences with *A. flavus.* Since ITS sequence is not
296 discriminatory to differentiate *A. flavus* from *A. parvisclerotigenus*, the sequences of
297 parts of beta-tubulin and calmodulin gene were determined and displayed 100%
298 identity with those of *A. parvisclerotigenus* (Table 2).
299

300 *3.1.2 Toxin pathway gene profile of fungal strains isolated from cassava*

301 To evaluate the toxigenic potential of *A. flavus* isolates, the presence of 6 different genes
302 (*AflD, AflO, AflP, AflQ, AflR* and *AflS*) involved in the aflatoxin biosynthetic pathway was
303 investigated by PCR. All the strains possessed these six genes in their genome (Table 3).
304 The ability of the strains to produce mycotoxins was then confirmed by AFB1 and AFG1
305 analysis after culturing in conditions known to favor mycotoxin synthesis. Table 3 shows
306 that most of the isolates were able to produce AFB1. Although the biosynthetic pathway
307 genes detection was positive, the culture extracts from two strains do not showed any
308 AFB1 trace. Four isolates identified as *A. novoparasiticus* (AFc31 and AFc32) and *A.*
309 *parvisclerotigenus* (AFc35 and AFc36) were also found capable to produce AFG1. These
310 results are in agreement with results of sequences analysis of *cypA*/*norB* region
311 reported above.
312

313 *3.1.3 Detection of aflatoxin B1 in cassava chips*

314 As shown in Table 2, despite the aflatoxigenic character of the *A. flavus* strains isolated
315 from cassava chips collected in Benin, no trace of AFB1 was detected neither in the chips
316 collected in the present survey nor in the samples obtained from the previous survey.
317
318 **3.2 Effect of cassava on *A. flavus* growth and toxinogenesis**
319
320 In order to understand the absence of contamination of cassava by AFB1 despite the
321 presence of toxigenic strains of *A. flavus*, the ability of cassava to inhibit AFB1 synthesis
322 was investigated.
323
324 *3.2.1 Effect of fresh cassava on aflatoxinogenesis*
325 One highly toxigenic strain of *A. flavus* isolated from cassava chips (strain AFc5) was
326 used to inoculate fresh cassava pieces of two varieties from different geographic origins.
327 As shown on Figure 2, fungal development was macroscopically visible after 3 and 6
328 days of incubation, whatever the variety of cassava was used. The measurement of the
329 ergosterol content in the cultures and spore formation confirmed that the *A. flavus* strain
330 AFc5 was able to develop on both cassava varieties (Table 4).
331 As expected from the survey data, the fungal development and sporulation was not
332 associated with AFB1 synthesis, regardless of the time and the cassava variety tested
333 (Table 4). A similar inhibition of AFB1 production was observed when toxigenic strains
334 belonging to three other *Aspergillus* section *Flavi* species (*A. parasiticus*, *A. bombycis* and
335 *A. pseudotamarii*) were grown on cassava (Table 5), although these strains produced
336 AFB1 when cultured on PDA medium.
337 The spiking of both fresh and autoclaved cassava with known amount of pure AFB1
338 demonstrated that the lack of AFB1 after *A. flavus* development on cassava was not
339 linked to a matrix interference. Indeed, 71 and 74% of the added toxin could be
340 recovered from fresh and autoclaved spiked samples respectively.
341
342 *3.2.2. Effect of cassava processing on AFB1 synthesis*
343 The impact of different processing used during the production or the storage of cassava
344 products were then tested for their effect on AFB1 synthesis.
345 Cassava pieces were submitted to different processing before inoculation with toxigenic
346 *A. flavus* strain AFc5. Figure 3 shows the effect of heat treatment on both mold

347 development and AFB1 synthesis. A small but significant increase in spore numbers
348 after development on heat-treated cassava was noted (Figure 3a). By contrast, no
349 difference was observed for ergosterol content with the exception of an increased value
350 after development of AFc5 strain on fresh cassava from Costa Rica for 6 days (Figure
351 3b). Regarding toxinogenesis, when the toxigenic strain was inoculated on heat-treated
352 cassava, AFB1 was detected after 3 (data not shown) and 6 days of incubation (Figure
353 3c) whereas no toxin was detectable after mold development on fresh cassava.
354 The effect of other process methods was also tested. Table 6 shows that sun drying of
355 cassava pieces may also interfere with the ability of this raw material to prevent AFB1
356 synthesis by a toxigenic strain of *A. flavus*. Indeed, after 7 days of drying, a re-moistening
357 of cassava chips allowed AFB1 production (5.5 ± 0.5 ng/g).
358 Similarly, we observed that a 2-month freezing period at -20°C inhibited the anti-AFB1
359 ability of cassava, the mycotoxin becoming detectable after inoculation with the
360 toxigenic strain Afc5 and incubation for 7 days at 25°C (42 ± 18 ng/g).
361

362 *3.2.3. Role of scopoletin in the inhibition of AFB1 synthesis*

363 Among constituents of cassava, scopoletin is known to have anti-fungal properties. Even
364 if no antifungal activity was noted, we nevertheless investigated if this compound could
365 explain the inhibition of AFB1 biosynthesis in fresh cassava.
366 Table 7 shows that there were no significant differences in the scopoletin concentration
367 in heat treated cassava compared to fresh one (p=0.159) whereas in the former
368 condition, AFB1 was detected after *A. flavus* development. The same results were
369 obtained using the two varieties of cassava that contained comparable concentrations of
370 scopoletin (Table 7).
371

372 ## 4. Discussion

373

374 Cassava is a major crop in many regions of the world where it is used as human food and
375 animal feed. The aim of this study was to assess the fungal and mycotoxin contamination
376 that could occur after harvest and during processing of cassava.
377 In order to characterize fungal contamination of cassava at the first step of the
378 processing chain, cassava chips were collected from several local producers in the north
379 of Benin. Almost 40% of the samples were contaminated with *Aspergillus* of the section
380 *Flavi* demonstrating that these fungal species may contaminate cassava before
381 processing. Among the 20 isolates from these samples, sixteen were identified as
382 *Aspergillus flavus*. All isolates previously collected from cassava on Benin markets were
383 also identified as *A. flavus*. This confirmed the data published by Gnonlonfin et al. (2008;
384 2012) which have identified *A. flavus* as a frequent contaminant of cassava chips
385 marketed in Benin as well as other studies done elsewhere in Africa (Manjula et al.,
386 2009; Westby et al., 1995; Essono et al., 2007). This is also in agreement with the
387 observation that *A. flavus* is more prevalent in foods and feeds than *A. parasiticus*
388 (Essono et al., 2009).
389 Most of the isolates produced aflatoxin B1 when cultured on PDA. This proportion of
390 toxigenic isolates appeared quite high compared to what is usually reported. Indeed, the
391 proportion of toxigenic *A. flavus* often ranges between 40% and 65% in raw materials
392 such as maize (Saleemi et al., 2012; Giorni et al., 2007), cocoa beans (Sanchez-Hervas et
393 al., 2008), groundnut (Bankole et al., 2004) or spices (El Mahgubi et al., 2013; Elshafie et
394 al., 2002). Four isolates were found able to produce aflatoxin G_1. These strains were
395 further identified as *A. parvisclerotigenus* and *A. novoparasiticus*.
396 This last species was recently discovered and characterized (Gonçalves et al., 2012).
397 With one exception, all strains have been isolated from patients and hospital
398 environment samples. So far, its geographical distribution was limited to South America
399 (Brazil and Colombia). This is the first report which mentions the presence of *Aspergillus*
400 *novoparasiticus* in another continent other South America. It is also the first time that
401 this species is isolated from food products.
402 Unlike *A. flavus*, *A. parvisclerotigenus* is a poorly documented species. Although the first
403 mention regards atypical isolates from tropical soils in Thailand (Saito and Tsurata,
404 1993) all isolates which were subjected to molecular characterization came from Guinea

405 Gulf area (Nigeria, Benin). Recently, five isolates were identified from dried edible
406 mushrooms in Nigeria (Ezekiel et al., 2013) while the Type strain (CBS 121.62) was
407 isolated from peanut, also in Nigeria (Frisvad et al., 2005). Blast analysis of *cypA*/*norB*
408 region sequences of AFc35 and Afc36 isolates displayed a 100% identity with those of
409 the type strain but also with those of BN008R (ATCC MYA-379) strain, an atypical S_{BG}
410 strain collected from agricultural soil in Benin (Cotty and Cardwell, 1999). *A.*
411 *parvisclerotigenus* occurrence observed in our study is very low (<6%) as already
412 described (Ezekiel et al., 2013).
413
414 Despite the high prevalence of contamination with toxigenic isolates, the analysis of
415 AFB1 contamination of cassava samples revealed no trace of this toxin in the chip
416 samples. Similar results were obtained on cassava chips sampled at the market stage in
417 Benin (Gnonlonfin et al*.,* 2012). This confirms that, in spite of a high occurrence of *A.*
418 *flavus* spores, cassava chips are not contaminated with aflatoxins.
419 This observation suggests that cassava may interfere with AFB1 production. To
420 characterize the interaction between cassava and aflatoxinogenesis, fresh cassava chips
421 were inoculated with spores of a highly toxigenic *A. flavus* strain. The fungus was able to
422 rapidly grow on cassava, and was macroscopically visible after 3 days of incubation. This
423 growth was confirmed by both ergosterol measurement and spore numeration.
424 Nevertheless, the fungal development on fresh cassava was not associated with AFB1
425 production. So it demonstrates that fresh cassava is able to block AFB1 production when
426 colonized by a toxinogenic strain of *A. flavus*. This inhibition of AFB1 production was
427 observed using 2 different varieties of cassava and with several AFB1 producing species
428 of the *Flavi* section. To the best of our knowledge, this is the first report indicating that a
429 raw material, which allows fungal development, may interfere with aflatoxin B1
430 synthesis. Cassava can therefore be considered as resistant to the contamination with
431 this mycotoxin. Plant extract/products have been described that inhibit AFB1
432 production. For instance, Yoshinari et al. demonstrated that German Chamomille blocks
433 aflatoxin G production (Yoshinari et al., 2008). Razzaghi-Abyaneh et al. (2009) also
434 showed that *Carum carvi L.* inhibits AF production without any obvious effect on fungal
435 growth. More recently, Gorran (2013) showed that an aqueous extract of *Thymus*
436 *daenensis* was able, at a concentration of 2000 mg/l, to reduce the production of AFB1
437 by 97%.

438 For cassava, our data suggest that cassava is a substrate non-permissive for secondary
439 metabolism. Indeed, HPLC analysis of extracts revealed that no peak corresponding to
440 secondary metabolites was observed on a chromatogram when the strain AFc5 was
441 grown on cassava in contrast to what was observed when the *A. flavus* strain was grown
442 on the usual media (PDA, MEA or YES) (data not shown). The absence of *A. flavus*
443 secondary metabolites despite normal growth suggests that cassava acts on the global
444 regulation of secondary metabolism. In the last decade, several transcription factors
445 have been found to regulate secondary metabolism in *A. flavus*. The alteration of
446 transcription factors is often linked to fungal development anomalies. An inhibition of
447 the recently described transcription factors nsdC and nsdD is very unlikely. Indeed, the
448 Δ*nsdC* and Δ*nsdD* mutants exhibit columnar arrangement of the conidial chains on the
449 conidiophores and shorter conidiophore stipes (Cary et al., 2012). In the present study,
450 no macroscopic or microscopic morphological alteration was observed when *A. flavus*
451 grew on fresh cassava. A heterotrimeric nuclear complex composed of three proteins
452 LaeA, VeA and VelB regulates the secondary metabolism (Bayram et al., 2008). LaeA has
453 a major effect on aflatoxin B1 synthesis in *A. flavus* as well as on the whole secondary
454 metabolism in other *Aspergillus* species (Kale et al., 2008). The disruption of *VeA* leads to
455 decreased activation of the aflatoxin biosynthesis pathway in *A. parasiticus* and *A. flavus*
456 (Calvo et al., 2004; Amaike and Keller, 2009). In *A. flavus*, VeA is also necessary for the
457 synthesis of cyclopiazonic acid and aflatrem (Duran et al., 2007). VelB regulates the
458 same biosynthetic pathway (aflatoxin/sterigmatocystin) in *A. nidulans* (Bayram et al.,
459 2008). In contrast to *nsdC* or *nsdD* genes, the deletion of *LaeA, VeA* or *VelB* only
460 marginally modifies the morphological aspect of the fungi. For instance, disruption of
461 *VelB* leads to a considerable decrease in conidia production whereas deletion of *VeA* or
462 *LaeA* only induces a slight decrease in spore numbers (Park et al., 2012). This reduction
463 of conidiogenesis is accompanied by a decrease in the growth diameter when the Δ*laeA*
464 or Δ*veA* mutants grow on a media plate. The deletion of both *LaeA* and *VeA* genes is
465 characterized by an inability to produce sclerotia. In the present study, when the *A.*
466 *flavus* strain AFc5 was grown on fresh cassava, we observed a small decrease in
467 sporulation and the absence of sclerote formation as well as an inhibition of whole
468 secondary metabolism. Despite the absence of an effect on fungal growth, these
469 observations suggest that fresh cassava may act on the velB/VeA/LaeA complex.

470 However, a further molecular study should be carried out in order to confirm this
471 hypothesis.
472 In order to better understand the mechanisms underlying the inhibition of AFB1
473 synthesis by cassava, the impact of several processes was studied. We observed that the
474 ability of cassava to block AFB1 production by a toxigenic strain of *A. flavus* was
475 inhibited by heat treatment, sun drying or freezing of cassava samples. When each of
476 these processes was applied, the growth of a toxinogenic strain of *A. flavus* on treated
477 cassava was associated with the production of AFB1. These assays demonstrated that
478 the molecule responsible for the inhibition of toxin production is quite sensitive and
479 could correspond to a peptide or small protein.
480 Among candidate compounds that may participate to AFB1 inhibition by cassava, the
481 role of scopoletin was investigated. This molecule is a thermostable coumarin
482 phytoalexin with medical properties. It is accumulated in some plants such as carrot
483 (Coxon et al., 1973), cotton (Zeringue, 1984), sunflower (Gutierrez et al, 1995), noni or
484 *Morinda Citrifolia* (Deng et al., 2010) and cassava (Buschmann et al., 2000) in response
485 to both biotic and abiotic stress (Edwards et al., 1997). It can also accumulate in roots
486 and tubers as a result of post-harvest physiological deterioration. This compound has
487 been reported to be a potent anti-microbial molecule with fungicidal properties
488 (Rodriguez et al., 2000; Gomez-Vasquez et al., 2004). In the present study, scopoletin
489 was not responsible for AFB1 inhibition. Indeed, thermal treatment (120°C, 20 min) did
490 not modify the scopoletin content of cassava chips whereas it restored AFB1 production
491 by toxinogenic *A. flavus* strain.
492 Similarly, cyanogenic compounds present in fresh cassava may not be involved in the
493 anti-aflatoxigenic ability of the product since the varieties used in our study were sweet
494 ones characterized by a low content of cyanogenic compounds. Moreover, many fungi
495 display natural linamarase activity and are therefore able to break down cyanogenic
496 glucosides present in cassava (Birk et al., 1996; Amoa-Awua et al., 1997).
497
498 In conclusion, this study demonstrated for the first time that fresh cassava can be
499 considered as a crop that is resistant to aflatoxin B1 contamination. This report is very
500 important as a food safety issue due to the importance of cassava in the diet of millions
501 of people. Indeed, it appears that cassava is naturally protected from AFB1
502 contamination during the pre-harvest period. This is usually a critical step regarding

503 mycotoxin synthesis due to the high water activity of plants. After that, since this ability
504 will be lost by cassava during drying, it is necessary to ensure good storage procedure
505 and avoid remoistening of chips. It is now important to identify the active compound(s)
506 and the precise mechanism of action in order to be able to inhibit toxin production
507 during processing and storage and to possibly use it in other applications.

Research Highlights

- Cassava is contaminated with toxigenic *Aspergillus flavus* but not by aflatoxin B1
- Cassava can be contaminated with *A. novoparasiticus*.
- Fresh cassava is able to block AFB1 synthesis by *Aspergillus flavus*
- But cassava does not modify *Aspergillus flavus* development
- Thermal treatment of cassava leads to a loss of the anti-aflatoxin ability
