Supporting Information

ABSTRACT: Among hormone-inducible transcription factors, estrogen receptors (ERs) play important roles in tissue growth and differentiation, via either direct or indirect binding, in the nucleus, to specific DNA targets called estrogen responsive elements (EREs), or through nongenomic pathways. In humans, two estrogen receptor isoforms (hERs), designated hER α and hER β , have been identified. These two hERs, encoded by genes located on distinct chromosomes, exhibit divergent tissue-specific functions and different subcellular distributions depending on their binding status, free or complexed to their cognate ligands. Because it is hypothesized that such distinct behaviors may arise from various conformational stabilities and flexibilities, the effect of salt concentration and temperature was studied on the free and estrogen-activated hER α and hER β . Our results show that the conformational stability of hER β is weakly modulated by salt concentration as opposed to hER α . In addition, we show that the estrogen-bound hERs exhibit a more constrained structure than the unliganded ones and that their conformational flexibility is more affected by diethylstilbestrol binding than that of estradiol, 4-hydroxytamoxifen, or raloxifen. In line with these results, conformational analysis and computational docking were performed on hER α and hER β , which confer molecular support of a diethylstilbestrol-induced restrained flexibility as compared to other ligands. We found that Trp383 in hER α and Trp335 in hER β can closely interact with the NR-box motif of the H12 helix and act as a gatekeeper of the agonist-bound versus antagonist-bound conformations. Altogether, our study contributes to an improved knowledge of the diverse physicochemical properties of full-length hERs, which will help in our understanding of their distinct cellular roles in various cellular contexts.

Estrogens, as primordial female steroid hormones, play important roles in the reproductive function via their action on organs such as breast, uterus, and prostate, and also in nonreproductive systems such as brain, bone, heart, and liver.¹ The physiological functions controlled by estrogens are partly mediated by the estrogen receptor (ER), a hormone-inducible transcription factor, localized in and/or out of the nuclear compartment. In the nuclear compartment, ER positively or negatively regulates the expression of genes involved in tissue growth and differentiation,^{2,3} either by directly binding on specific DNA sequences located in the promoters of target genes or by interacting with other transcriptional factors in the nucleus. The extranuclear ER exerts rapid nongenomic actions that are usually associated with the activation of various protein kinase cascades.⁴ A dysregulation of ER signaling is associated with breast cancer.

The first human ER identified, designated hER α , was cloned from MCF-7 cells where it is overexpressed.⁵ A few years later, a second ER, designated hER β , was identified in different human organs.^{6,7} In humans, separate genes located on distinct chromosomes encode these two subtypes.⁸ These estrogen receptors exhibit specific tissue distributions, biological roles,^{9,10} and ligand affinities for various endogenous estrogens.¹¹

The two hERs exhibit distinct subcellular distributions, while forming different protein transitory complexes and being involved in separate functional regulations mainly because they are involved in the regulation of a distinct set of genes.^{12,13}

Actually, hER α is essentially localized in the nucleus^{14–16} whereas hER β is found in the nucleus and mitochondria.¹⁷ In mitochondria, hER β regulates the expression of proteins related to the oxidative phosphorylation.¹³

Human ER α and ER β are 66 and 55 kDa proteins, respectively, that share a modest (47%) overall sequence identity.⁶ Human ER β exhibits a truncated sequence at the N- and C-terminal extremities. The most conserved domains are the DBD and LBD, DNA and ligand binding domains (also called C and E domains), with 94 and 59% identity, respectively; these domains are also well-conserved among different species. The DBD is highly stabilized by two zinc fingers. The first one specifically interacts with oligonucleotide sequences called estrogen responsive elements (EREs), whereas the second one is responsible for dimerization of the DBD and the orientation of the first zinc finger.¹⁸ The LBD, comprising a hormone binding site, a dimerization interface, and a coregulator interaction function, exhibits a helical structure. Its 11 α -helices are organized in a three-layer sandwich structure with H4, H6, H8, and H9 forming one layer flanked on one side by H1 and H3 and on the other side by H7, H10, and H11. The H12 helix undergoes a differential repositioning upon ligand binding, adopting a unique conformation compatible with coactivator binding in both agonist-bound ER isotypes.^{19,20} The other domains, A/B, D, and F, share 17, 30, and 18% identity, respectively, and are generally considered to be flexible.

The classical model of transactivation of ER requires not only estrogen binding, releasing of ERs from inactive complexes, dimerization, and DNA binding processes but also translocation toward the nuclear compartment and transcription activation processes. Actually, estrogen binding initiates the release of ER from inactive complexes,²¹ which consequently induces its dimerization, translocation to the nucleus, and its sequence-specific binding to ERE.^{14–16} Once bound to its specific target sequence, ER dimer interacts with a series of coregulators.^{22–24} These ER–coregulator complexes affect the chromatin structure and modulate the RNA polymerase II recruitment and activity. These partners may bind to the ER N-terminal end or to the LBD region;^{22,23} thus, the transcription activation function is hormone-independent (AF-1) or hormone-dependent (AF-2).²⁵

Despite the numerous structural data available about human ERs, obtained by using either the full-length receptor or partial constructs, little information has been gathered concerning the thermodynamic parameters of the molecular interactions responsible for the stabilization of the functionally effective conformations. The knowledge of these energetic features is essential for understanding their distinct cellular behaviors. Thus, our study, while mainly focused on the thermodynamic stability differences between the two hERs and the contribution of the electrostatic network to their respective flexibility and functionality, also takes into account the molecular features that could explain these discrepancies. This study shows that hER α and hER β distinctly respond to charge screening. In other words, the compromise between conformational stability and flexibility varies from one form to the other; consequently, this likely alters their binding status, i.e., their respective set of interactions with other partners such as coregulators, and makes them distinctly sensitive to any ionic strength variation. Conformational analysis of yet unsolved complexes combined with our *in silico* docking studies substantiates these differences and is reported here. Hence, a better knowledge of the

physicochemical properties of both human ERs combined with structural highlights might allow a better understanding of the role of each hER and, in the future, may be useful for the development of new drugs designed to prevent or cure breast cancer.

■ EXPERIMENTAL PROCEDURES

Reagents and Buffer Solutions. All reagents were obtained from Sigma (St. Louis, MO) or Carlo Erba Reactifs (Val de Reuil, France) unless indicated otherwise. The steroid compounds used in this study, E2, DES, 4-OHT, and RAL, were solubilized in ethanol, except for RAL, which was solubilized in DMSO. The steroid stock solution concentration was 10^{-5} M. The buffer solution was 10 mM Tris-HCl with KCl at various concentrations (80, 140, or 200 mM) (pH 7.5), 0.1 mM EDTA, 1 mM DTT, and 10% glycerol.

Recombinant Proteins. Full-length purified recombinant human ER α and ER β (rhER α and rhER β , respectively), baculovirus-expressed, were purchased from Invitrogen (Cergy-Pontoise, France) and stored at -80 °C. The protein concentrations of ER α and ER β were 2.6×10^{-6} and 4.5×10^{-6} M, respectively. The purity of ER samples was checked by the standard method using sodium dodecyl sulfate–polyacrylamide gel electrophoresis followed by Coomassie Brilliant Blue R250 staining. The possible post-translational modifications (PTMs) of both commercial ERs have been checked by using two kits following the manufacturer's recommendations: Pro-Q Diamond phosphoprotein gel stain and Pro-Q Emerald 488 glycoprotein Gel and blot stain kit (Invitrogen). One hour before every experiment, each protein sample was thawed and diluted to 7.5×10^{-7} M in assay buffer. This pre-equilibration time is required for protein stabilization. Protein samples, buffers, and other solutions were kept on ice for the duration of the experiments.

Fluorescein-Labeled Oligonucleotides. Double-stranded oligonucleotide solutions were prepared from two 21 bp complementary oligonucleotidic sequences that were coupled to fluorescein at the 5' end. These oligonucleotides were synthesized, purified, and adjusted to 100 μ M by Proligo (Paris, France). The sequences of the sense strand of palindromic consensus ERE (ERE_{cs}), natural rainbow trout ERE (*rtvtg*ERE), and nonspecific oligonucleotide (OLNs) are 5'-GTCAGGTCACAGTGACCTGAT-3', 5'-AGTGGGG-CAGGTTAACCTAAC-3', and 5'-CCCACGTAATAACTGC-CATCC-3', respectively. The *rtvtg*ERE degenerated sequence was previously identified in our laboratory in the promoter region of *Oncorhynchus mykiss* vitellogenin genes.²⁶

The duplexes were formed by diluting each oligonucleotide in assay buffer [10 mM Tris-HCl, 80 mM KCl, 0.1 mM EDTA, 1 mM DTT, and 10% glycerol (pH 7.5)] to reach a final oligonucleotide concentration of 1 μ M. Then, both complementary oligonucleotides were mixed and heated to 85 °C for 10 min and slowly cooled to 4 °C.

Steady-State Fluorescence Experiments. All experiments were conducted with recombinant human ERs at 10 ± 2 °C except for the thermal stability experiments. Steady-state fluorescence emission was measured by using an SLM8100 spectrofluorimeter. Spectra and anisotropy values were corrected by subtracting the contribution of the buffer solution to the signal. All experiments were repeated independently at least three times.

ER–ERE Equilibrium Constants. To determine the effect of the salt concentration on the complexes formed between

rhER α (or rhER β) and different ERE sequences, the fluorescence anisotropy values of fluorescein covalently bound to oligonucleotides were measured as a function of rhER concentration.

Fluorescein-labeled oligonucleotide fluorescence anisotropy values were monitored with an excitation wavelength of 480 nm and a bandwidth for excitation of 2 nm; the fluorescence emission intensities were collected through a 515 cutoff Oriel filter, which removes the excitation light scattering. The emission anisotropy, A , was calculated according to

$$A = \frac{F_{VV} - F_{VH} \left(\frac{F_{HV}}{F_{HH}} \right)}{F_{VV} + 2F_{VH} \left(\frac{F_{HV}}{F_{HH}} \right)} \quad (1)$$

where F_{12} features the emission fluorescence intensity with subscripts 1 and 2 indicating the vertical and horizontal position of the excitation and emission polarizers, respectively. Fluorescence anisotropy measurements were taken with an integration time of 5 s on each emission intensity component.

For rhER–oligonucleotide binding titration experiments, the oligonucleotide concentration was kept constant at 10^{-9} M and the protein concentration varied between 2×10^{-10} and 3×10^{-8} M. Prior to the collection of anisotropy values, the sample (oligonucleotide plus protein) was incubated for 10 min to allow protein–oligonucleotide complexation. These binding titration experiments were performed in the presence of 80, 140, or 200 mM KCl.

The dissociation constant, K_D , of the rhER–ERE equilibrium is recovered by fitting the binding titration curve to the equations below assuming that, within the protein concentration range used, only one equilibrium is observed:

$$A = \frac{K_D A_{DNA^*}}{[rhER] + K_D} + \frac{[rhER] A_{DNA^*-rhER}}{[rhER] + K_D} \quad (2)$$

with A_{DNA^*} and A_{DNA^*-rhER} are the anisotropy values of fluorescein-labeled oligonucleotide and fluorescein-labeled oligonucleotide covalently bound to rhER, respectively, and $[rhER]$ is the concentration of free rhER.

Because the concentration of oligonucleotide is slightly lower than the K_D value in some experiments, the equation used for data fitting and recovering the K_D value is

$$A = \left[1 - \frac{\left(\left([DNA^*] + [rhER] + K_D \right) - \sqrt{\left([DNA^*] + [rhER] + K_D \right)^2 - 4[rhER][DNA^*]} \right)}{2[DNA^*]} \right] A_{DNA^*} + \left[\frac{\left(\left([DNA^*] + [rhER] + K_D \right) - \sqrt{\left([DNA^*] + [rhER] + K_D \right)^2 - 4[rhER][DNA^*]} \right)}{2[DNA^*]} \right] A_{DNA^*-rhER} \quad (3)$$

Values of the dissociation equilibrium constant (K_D) were obtained by nonlinear least-squares curve fitting using the commercial Peakfit software.

rhER Flexibility. To probe hER relative flexibility, as free or complexed forms, the effect of salt concentration and ligand binding was investigated through the monitoring of the dynamic accessibility of tryptophanyl residues by fluorescence quenching experiments.

Tryptophan fluorescence quenching experiments were conducted by using acrylamide, which is known to be an efficient quencher of tryptophanyl fluorescence.^{27,28} Fluorescence spectra were recorded with bandwidths fitted for excitation and emission resolution of 4 and 2 nm, respectively. The excitation wavelength was 290 nm to ensure that the

measured fluorescence was due to the sole tryptophanyl residues. Fluorescence emission intensity was collected with an integration time of 1 s, between 300 and 430 nm. Each displayed spectrum is the average of four acquisitions.

These experiments were conducted at 5×10^{-8} M rhERs and various acrylamide concentrations from 0 to 0.17 M. Stock acrylamide solutions (2 M) were obtained by dissolving acrylamide (Sigma) in assay buffer. Experiments with ligands were performed at 140 mM KCl in the presence of E2, DES, 4-OHT, or RAL at a final concentration of 10^{-7} M to achieve 99% rhER complexation.¹¹

The quenching of fluorescence of fluorophore residues in proteins can occur in two ways: (i) static quenching arising from the formation of a complex between the fluorophore and the quencher before excitation and (ii) dynamic quenching resulting from encounters of fluorophore and quencher molecules during the excited-state lifetime. When both occur, the quenching process can be analyzed according to the modified Stern–Volmer equation:

$$\frac{F_0}{F} = (1 + K_{SV}[Q])(1 + K_a[Q]) \quad (4)$$

where F_0 and F are the fluorescence intensity in the absence and presence of the quencher Q , respectively, and K_{SV} and K_a are the collisional and static quenching constants, respectively. If a single process is operating or dominating, the plot of F_0/F versus $[Q]$ is linear; if both processes occur, the plot of F_0/F versus $[Q]$ exhibits an upward curvature.

For proteins having several fluorophore residues, the quenching data can be described by Lehrer's equation:

$$\frac{F_0}{\Delta F} = \frac{1}{f_a K_{SV}[Q]} + \frac{1}{f_a} \quad (5)$$

where $\Delta F = F_0 - F$ is the fluorescence intensity decrease observed at quencher concentration $[Q]$, f_a the fractional maximum of the accessible fluorophores, and K the quenching constant. For dynamic quenching, the constant K_{SV} is equal to the product $k_q \langle \tau \rangle$, where k_q is the bimolecular collisional rate constant and $\langle \tau \rangle$ the average fluorescence lifetime in the absence of quencher. The fraction of the accessible fluorophores was determined from the y -intercept of the plot of $F_0/\Delta F$ versus $1/[Q]$ and the apparent quenching constant from the ratio of the y -intercept to the slope.

rhER Thermal Stability. To measure the effect of salt concentration on the stability of the two human estrogen receptor isoforms, the fluorescence intensity of tryptophanyl residues in rhERs was monitored as a function of temperature. The fluorescence intensities were measured by exciting the protein sample at 290 nm and collecting the emission at 338 nm. These experiments were performed by increasing the temperature from 5 to 55 °C with a 3 °C step, and the signal was recorded 10 min after the temperature had been increased. To obtain the apparent T_M and the enthalpy change (ΔrH) of unfolding of hERs, the data were fit by using a two-state ($N \leftrightarrow D$) or a three-state ($N \xrightleftharpoons{K_1} I \xrightleftharpoons{K_2} D$) model according to the following mathematical equations:

$$I_{obs} = \frac{1}{1 + K} (I_N + KI_D), \text{ where } K = e^{\frac{\Delta rH}{RT} - \left(\frac{T}{T_M} - 1 \right)} \quad (6)$$

or

$$I_{\text{obs}} = \frac{1}{1 + K_1 + K_1K_2} (I_N + K_1I_I + K_1K_2I_D) \quad (7)$$

with

$$K_1 = e^{\frac{\Delta rH_1}{RT} \left(\frac{T}{T_{M1}} - 1 \right)}$$

and

$$K_2 = e^{\frac{\Delta rH_2}{RT} \left(\frac{T}{T_{M2}} - 1 \right)}$$

where I_N , I_I , and I_D are the fluorescence intensities of the native, intermediary, and denatured hER forms, respectively. K and ΔrH are the protein unfolding equilibrium constant and the apparent van't Hoff enthalpy of unfolding, respectively. T_M is the temperature at the midpoint of the unfolding transition. I_N , I_I , I_D , ΔrH , and T_M values were recovered from nonlinear least-squares curve fitting using the commercial Peakfit software. The displayed values of T_M and ΔrH are the apparent values because of the nonreversibility of the observed unfolding process.

Time-Resolved Fluorescence Measurements. Tryptophan fluorescence lifetime measurements were taken with a Fluoromax-3 fluorescence spectrophotometer from Horiba-Jobin-Yvon (Longjumeau, France). An electroluminescent diode with a pulse width of 800 ps was used for excitation, and a Hamamatsu model R928 photomultiplier was used to detect the fluorescence. Samples were excited at 280 nm, and emission intensities were recorded at 338 nm. Slit widths of the excitation and emission monochromators were 15 and 10 nm, respectively. The decay curves were analyzed by three-exponential iterative fitting program Daf6 (Horiba Scientific). The mean lifetime was calculated from

$$\langle \tau \rangle = \frac{\sum_i \alpha_i \tau_i^2}{\sum_i \alpha_i \tau_i} \quad (8)$$

where α_i is the molar fraction of component i and τ_i is the lifetime of each discrete exponential component.

Molecular Modeling Docking. The crystal coordinates of the human ER α LBD in complex with E2 [Protein Data Bank (PDB) 1g50],²⁹ DES (PDB entry 3erd),³⁰ 4-OHT (PDB entry 3ert),^{30,31} and RAL (PDB entry 1err)³² were retrieved from the PDB. The interaction energy between hER α LBD and ligands, agonist, or SERM was evaluated for each crystal complex with the CHARMM force field³³ and “smart minimizer” module, implemented in DiscoveryStudio (Accelrys Software). Similarly, the crystal coordinates of the human ER β LBD in complex with E2 (PDB entry 3oll)²⁰ and 4-OHT (PDB entry 2fsz)³⁴ were retrieved from the PDB, and the interaction energy was computed within the same protocol. For missing DES–ER β and RAL–ER β complexes, the coordinates of human agonist-bound DES–ER α and RAL–ER α complexes were superimposed onto agonist-bound E2–ER β and SERM-bound 4-OHT–ER β complexes, respectively, using the SSM (Secondary Structure Matching) module implemented in Coot version 0.7.2.³⁵ That superimposition gave accurate starting positions of DES and RAL in the ER β LBD that were subsequently minimized using the CHARMM force field and “smart minimizer” protocol, with no constraint on ligand or side chains. Similarly, the interaction energy was computed. All crystal and *in silico* complexes were then visually inspected using Pymol (The PyMOL Molecular Graphics System, version 1.5.0.2, Schrödinger, LLC).

RESULTS

We have previously shown that the interaction between rhER α and its ERE targets depends on the conformational flexibility of rhER α .³⁶ This work aims to characterize the factors that significantly contribute to the conformational stability of the two hER isoforms and, consequently, to their biological function. To this end, we used commercial rhERs, expressed in insect cells, which are both phosphorylated and unglycosylated (Figure S1 of the Supporting Information). To determine how the electrostatic network of human ERs, free and estrogen-bound forms, modulates the conformational stability and flexibility, the effect of salt concentration was investigated at pH 7.5. Upon analysis of hER amino acid sequences, hER β (+12.7) appears to be more positively than hER α at this pH value (+4.5).

The Interaction between rhER β and EREs Is Ruled by Electrostatic Interactions. The ability of rhER β to interact with different ERE sequences has been monitored by using the fluorescence anisotropy methodology. This technique allows evaluation, in solution, of the impact of physicochemical parameters on the interaction between molecules.^{37–40} For this study, binding of rhER β to two oligonucleotide target sequences, consensus and imperfect EREs, was conducted with a 21 bp double-stranded oligonucleotide labeled at the 5' end with fluorescein. The ERE consensus, ERE_{cs}, bears the palindromic AGGTCA half-site separated by 3 bp from the other site. The imperfect ERE, *rtvtg*ERE, has been identified in the intergenic region of the rainbow trout vitellogenin gene.

In this study, the effect of KCl concentration on the interaction between rhER β and both ERE sequences has been investigated. The fluorescein-labeled EREs were titrated with rhER β until the anisotropy value reached a plateau, which reflects the saturation of the binding sites. The resulting ERE–ER binding curve was fitted with eq 3 to determine the K_D values. Figure 1 displays the effect of KCl concentration on the

Figure 1. Fluorescence anisotropy profiles of fluorescein-labeled ERE upon rhER β binding. Titrations of 1 nM labeled ERE_{cs} and *rtvtg*ERE are performed at various KCl concentrations: 80 (●), 140 (■), and 200 mM KCl (▲). Experimental conditions: 10 mM Tris-HCl buffer (pH 7.5), 10% glycerol, 0.1 mM EDTA, and 1 mM DTT at 10 °C. The lines through the data result from data fitting using a single-equilibrium model (eq 3).

interaction between rhER β and ERE_{cs}. The binding curve is displaced toward the high protein concentrations as the KCl concentration increases, which indicates that the affinity of the complex decreases at high salt concentrations. Because the electrostatic interactions are weakened by the salt counterions, this result shows that the rhER β –ERE_{cs} interaction is essentially ruled by electrostatic forces. A similar result is

observed for the interaction of rhER β with an imperfect ERE (Figure 1). As expected, rhER β exhibits a lower affinity for *rtvtg*ERE than for ERE_{cs}. Furthermore, the salt effect is more pronounced for the rhER β –*rtvtg*ERE complex than for the rhER β –ERE_{cs} complex. This result indicates that the nature and/or number of electrostatic interactions stabilizing the two complexes differs. Table 1 displays the different recovered K_D

Table 1. K_D Values for rhER–ERE Interactions

values for both receptors. Whatever the ERE sequence and whatever the salt concentration, our results show that rhER α exhibits an affinity for ERE sequences higher than that of rhER β . The modulation of complexes affinities by salts is slightly more pronounced for rhER β than for rhER α .

rhER α and rhER β Electrostatic Networks. It is generally accepted that an increased thermal stability is due to an increased number of electrostatic interactions (ion pairs, H bonds, etc.).⁴¹ Thus, temperature-induced unfolding experiments of rhERs have been undertaken to report the relevance of the electrostatic network within these two isoforms. This was achieved by collecting the fluorescence emission of tryptophanyl residues after heating the protein samples from 5 to 55 °C. Following an increase in temperature, the total intensity decreases (Figure 2A). This temperature-induced fluorescence

Figure 2. Thermal unfolding of rhER β . (A) Fluorescence emission spectra of recombinant human ER β as a function of temperature ($\lambda_{\text{exc}} = 290$ nm). (B) Relative fluorescence intensity of rhER β in the presence of 200 mM KCl ($\lambda_{\text{em}} = 338$ nm). The data were fitted according to two models (eq 7): a two-state model (---) and a three-state model (—). The data are best fitted with a three-state model as shown from the R^2 value (0.99550) compared to the two-state model ($R^2 = 0.99050$) and from a less structured residual.

emission decrease has been analyzed according to a two-state model and a three-state model. Whatever the isoform, the best fit is obtained with a three-state model (Figure 2B and Figure S2 of the Supporting Information). As shown in Figure 3, this temperature-driven biphasic unfolding pattern is observed for rhER α and rhER β regardless of the KCl concentration. The thermodynamic parameters of hER unfolding have been

Figure 3. Thermal unfolding curve of rhERs as a function of salt concentration. The Trp relative fluorescence intensity was monitored at 338 nm as a function of temperature (pH 7.5; $\lambda_{\text{exc}} = 290$ nm). KCl concentrations were 80 (●), 140 (■), and 200 mM (▲). The data were fitted according to a three-state model.

recovered by curve fitting according to a three-state model (Table 2). As the thermal unfolding of hERs is not reversible under our experimental conditions (data not shown), the thermodynamic parameters determined are apparent values. The rhER α transition midpoints of thermal denaturation, T_M , decrease as KCl concentration increases, indicating a reduced thermal stability of rhER α in the presence of high salt concentrations. This result is in agreement with the fact that the higher the salt concentration, the less numerous the electrostatic interactions and subsequently the less stable the protein. For rhER β , the thermal denaturation is weakly altered by KCl concentration within the range investigated here. These data indicate that the thermal unfolding process of rhER α is highly sensitive to salt concentration compared to that of rhER β . Furthermore, regardless of the salt concentration, rhER α T_M values are greater than that of rhER β , which indicates that the overall stability of rhER α is higher than that of rhER β . These biophysical data are in agreement with the crystal structures of the E2–hER α ^{19,29} and E2–hER β ²⁰ LBDs, which both display numerous and highly accessible positively charged Arg and Lys and negatively charged Asp and Glu residues (Figure S3 of the Supporting Information). Moreover, both isoforms form LBD homodimers, which are highly stabilized by electrostatic interactions involving helices H10 and H11 at their interface (Figure S3 of the Supporting Information). One can hypothesize that a high salt concentration could screen the electrostatic interactions, notably the ones located at the dimer interface, thus destabilizing the dimer and modifying the positioning of helices H10 and H11 and leading to enhanced instability.

Electrostatic Interactions Contribute to the rhER Conformational Flexibility. On the basis of sequence analysis (Figure 4A), hER α contains five tryptophanyl residues: one residue located in the DBD (C domain), another in the hinge region (D domain), and the others in the LBD or E domain (Figure 4B, left). Human ER β contains seven tryptophanyl residues: four in the LBD [three at equivalent positions of hER α (see Figure 4B, right)], another in the DBD (at equivalent position of hER α), and two in the N-terminal region of the protein.

The ER flexibility was assessed by the dynamic accessibility of protein tryptophan to the acrylamide. This neutral quencher is able to diffuse inside the hydrophobic core of the proteins, allowing hence collision with the tryptophanyl residues. The

^aBecause the unfolding is not reversible, the determined T_M and ΔrH are apparent values. The recovered values derive from data fitting by using a three-state model. ΔrS has been calculated by using $\Delta rS = (\Delta rH)/T_M$. Experimental conditions are as follows: $\lambda_{exc} = 290$ nm, and $\lambda_{em} = 338$ nm.

Figure 4. Positions of tryptophan residues within the hER α and hER β isoforms. (A) The position of the tryptophanyl residues is represented along the simplified primary structure of the two estrogen receptor isoforms. The tryptophanyl residues found in an α -helix are shown by the α -helix number between parentheses. The secondary structure of the DBD and LBD of hERs is schematically shown: helices are shown as cylinders and β -strands as arrows. (B) Structure of the DBD of both hERs shown as a gray cartoon. The tryptophanyl residues are highlighted as orange dots and sticks, and helix H12 is shown as a red cartoon. The ligand estradiol is shown as blue sticks. Insets are the close views of the NR-box of H12 LxxLL contacting the tryptophanyl residues W383 in hER α and W335 in hER β LBD. The first x is a tyrosine residue in the LBD of both hERs that can be phosphorylated. Those tryptophanyl residues line the agonist binding pocket. This figure was created with Pymol.

fluorescence emission spectra of tryptophanyl residues were collected at increasing concentrations of acrylamide (data not shown). The corresponding Stern–Volmer plots [$F_0/F = f([\text{acrylamide}])$] are displayed in Figure 5. Within the used acrylamide concentration range, the Stern–Volmer plots are linear, indicating that the observed quenching occurs mainly via

a dynamic process. Regardless of the rhER and KCl concentrations, every tryptophanyl residue is quenched by acrylamide. Table 3 displays the K_{SV} values calculated from the slope of the curves (see eq 5). From the time-resolved fluorescence experiments, the decay curves have been analyzed by using a three-exponential model. The average lifetime $\langle \tau \rangle$,

	K_{SV} (mol ⁻¹ L)	k_q (mol ⁻¹ L s ⁻¹)	K_{SV} (mol ⁻¹ L)	k_q (mol ⁻¹ L s ⁻¹)
80	9.4 ± 0.3	1.72 × 10 ⁹	10.0 ± 0.3	1.82 × 10 ⁹
140	8.5 ± 0.2	1.56 × 10 ⁹	9.5 ± 0.5	1.73 × 10 ⁹
200	7.8 ± 0.2	1.43 × 10 ⁹	9.0 ± 0.3	1.64 × 10 ⁹

^aExperiments were performed at 10 ± 2 °C in 10 mM Tris-HCl (pH 7.5), 0.1 mM EDTA, 1 mM DTT, and 10% glycerol. Abbreviations: K_{SV} , Stern–Volmer constant; k_q , bimolecular collisional rate constant calculated by using an average lifetime values ($\langle\tau\rangle$) of 5.45 ns for rhER α and 5.48 ns for rhER β .

calculated from eq 8, has been used to determine the collisional rate constant between acrylamide and tryptophan residues. Whatever the rhER isoform used, the collisional rate constant decreases as the salt concentration increases, indicating that the dynamic accessibility of tryptophan residues is reduced at high salt concentration. Furthermore, the dynamic accessibility of tryptophanyl residues inside rhER α is slightly lower than that of rhER β , indicating that the latter exhibits a less constrained conformation.

Effect of Ligand Binding on rhER Flexibility. Previous studies have reported that the LBD structural plasticity allows the binding of various steroid ligands.^{42,43} Among them, three categories of steroid ligands, called agonists, antagonists, and SERMs, induce upon binding distinct conformational changes such as the repositioning of helix 12.^{32,44} The orientation of this helix modulates coactivator binding.^{22,23}

This study included fluorescence quenching and time-resolved fluorescence experiments to investigate the effect of agonists (E2 and DES) and SERMs (4-OHT and RAL) on the entire protein flexibility through the measurement of the dynamic accessibility of tryptophanyl residues. This work has been performed in the presence of 140 mM KCl. As shown in Figure 6, in absence or presence of ligand, all the fluorescent

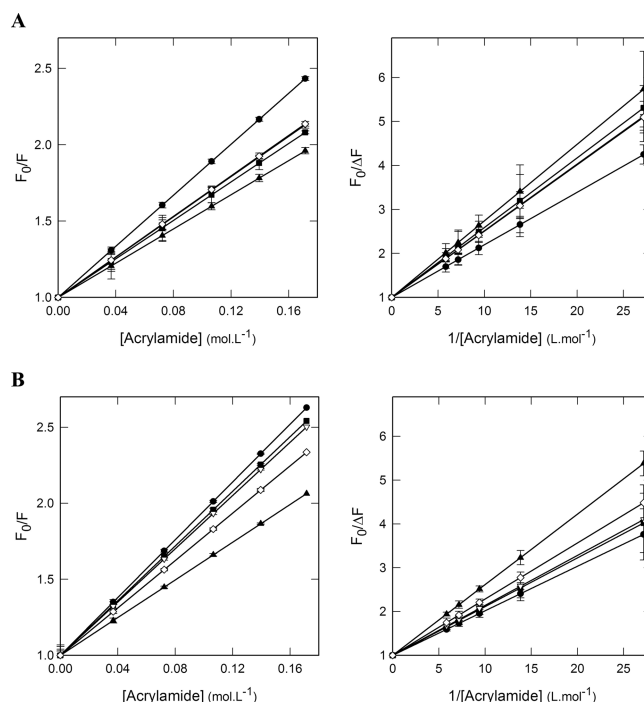

Figure 6. Fluorescence quenching of rhERs by acrylamide in the presence or absence of ligand: (A) rhER α and (B) rhER β . Symbols: (●) no ligand, (▲) E2, (■) DES, (▽) 4-OHT, and (◇) RAL. Left panels are Stern–Volmer plots [$F_0/F = f([\text{acrylamide}])$]. Right panels are Lehrer plots [$F_0/\Delta F = f(1/[\text{acrylamide}])$]. Experimental conditions: 140 mM KCl, pH 7.5, and 10 °C.

tryptophanyl residues are accessible and the observed quenching is mostly dynamic in nature. Table 4 displays the K_{SV} and k_q values obtained for both rhERs, complexed to ligands or not. In the presence of ligands, the k_q values are lower than that observed in the absence of ligand. This finding indicates that the dynamic accessibility of tryptophanyl residues within the hERs is reduced upon ligand binding. Besides, regardless of the complexation state and the bound ligand, rhER β is less constrained than rhER α . Furthermore, no specific effect associated with a particular ligand category has been observed on the flexibility of rhERs. Interestingly, our structural analysis evidenced that hER α Trp383 and hER β Trp335 are gatekeeper residues that distinguish active conformations (agonist-bound) from inactive conformations (apo or antagonist/SERM-bound conformations). Indeed, those tryptophanyl residues are quenched upon agonist binding as they closely interact with activation helix H12 (Figure 4B). Agonist binding promotes the proper positioning of helix H12 through the NR-box association. NR-box is a consensus LxxLL motif, where x can be any amino acid residue (see insets in Figure 4B, left and right). Agonist binding triggers adequate positioning of helix H12 to promote a hydrophobic groove at the surface of LBD where the coactivator can thus bind.

DISCUSSION

Regulation of gene expression by estrogen receptors involves successive events such as estrogen binding, release of ERs from inactive complexes, binding of dimeric ERs to EREs located in the promoters of ER-regulated genes, and recruitment of coregulators. ERs may also regulate the expression of target genes by binding to DNA sequences as a heterologous dimer formed with other nuclear transcriptional factors. Besides these genomic effects, ERs are involved in the nongenomic actions of estrogens associated with rapid signal transduction. These distinct estrogen-mediated biological functions, occurring in distinct cellular compartments, imply that ERs exist under different forms within these compartments (nucleus, cytosol, mitochondria, and/or cell membrane). Today, two isoforms of the human estrogen receptor have been identified, hER α and hER β . These two hERs, when expressed in the same cell type or organ, exhibit distinct abundances depending on the physiological and/or developmental states and different spliced isoforms. Additionally, these two hERs can display not only a tissue-specific expression but also an estrogen-mediated specific biological function within the tissue. Expressed together, they preferentially form heterodimers,⁴⁵ which, as a consequence of their reduced efficiency in recruiting coactivators,⁴⁶ show a transcriptional activity lower than that of the hER α homodimer. In MCF-7 and HeLa cells, it is fairly well stated that hER α accumulates in the nucleus even in the absence of ligand, and some nuclear punctuate patterns containing the receptor appear following hormonal stimulation.^{14–16} As our understanding of the factors that regulate in particular hER intracellular trafficking and assembly within large complexes mainly relies on our knowledge of the physicochemical features of hERs observed *in vitro*, we studied the stability and flexibility of these two phosphorylated purified full-length receptors, hER α and hER β .

As previously reported, at low salt concentrations, hER α and hER β strongly interact with ERE consensus or degenerated sequences; the specificity of these complexes is enhanced by increasing salt concentrations.^{36,37,39} Formation of the complex between hERs and ERE_{cs} is little affected by salt concentration. Actually, between 80 and 200 mM KCl, the K_D value of these hER–ERE_{cs} complexes remains in the nanomolar range (<10 nM). The effect of salt on formation of the complex between hERs and *rtvtgERE* is more pronounced: at 200 mM KCl, the K_D value of this complex is >40 nM. This salt effect well matches the stabilization of hER–ERE complexes by direct and water-mediated hydrogen bonds.^{18,47} Indeed, it has been shown that the interaction between hER residues and ERE phosphate groups requires more water molecules, i.e., more water-mediated H bonds for an imperfect ERE than for the ERE_{cs}.⁴⁷ Additionally, regardless of the KCl concentration, hER α exhibits a slightly higher affinity for both ERE_{cs} and

rtvtgERE as compared to that of hER β . As the highest hER α affinity for ERE cannot be explained by Newtonian attraction between ER and DNA (hER α being less positively charged at pH 7.5 than hER β), this difference in affinity can be assigned to a constrained DNA conformation within hER–ERE complexes. Actually, ERE undergoes a bending upon hER α complexation, whereas little constraint was observed with hER β .⁴⁸ Besides, it was shown that both hER α and hER β interact with the same nucleotides of ERE_{cs}.⁴⁹ Hence, the ERE bending, specifically induced by the binding to hER α , might arise from a restricted protein flexibility. From the fluorescence quenching experiments presented here, it appears that all fluorescent tryptophanyl residues exhibit a homogeneous dynamic accessibility regardless of their localization in both hERs, and more importantly, it appears that hER α flexibility is lower than that of hER β . This result agrees well with the observed ERE bending within the hER α –ERE complex and with crystallographic data. Actually, structural studies evidence, in both LBDs of ERs, that flexibility is driven by equilibrium between the agonist-bound active conformation and antagonist-bound inactive conformation and fluctuates upon ligand binding. Notably, the fact that hER α *ν* ever crystallizes in the apo form evidences its intrinsic flexibility, the latter being enhanced in the absence of ligand.²⁹ Similarly, the LBD of hER β shows remarkable flexibility in light of the different positions adopted by helix H12, as well as regarding the missing electronic density at the C-terminus of helix H11 in the crystal forms of E2–ER β (PDB entry 3oll) and 4-OHT–ER β (PDB entry 2fsz) complexes. As previously shown with hER α , a KCl concentration increase, within physiological range, leads to restricted fluctuations within the hER β protein.³⁰ Increasing the salt concentration also has consequences for hER thermal stability, this effect being more pronounced, mainly at low salt concentrations, for hER α . This differential salt dependence well matches their respective electric charge. Moreover, the thermal unfolding process of both hERs reveals the existence of an intermediate state as already reported by far-UV circular dichroism spectroscopy.^{50,51} Because this partially unfolded conformation is observed at physiological temperature, it must be relevant in the cell physiological and physicochemical context. One may infer that any variation in ion flux within a given subcellular compartment must displace the hER folding equilibrium with consequences for both conformational stability and flexibility of hERs.

Upon hormone binding, estrogen receptors undergo conformational changes essential for their transcriptional activity. However, it has been reported that binding of the ER to ERE is not systematically dependent on ligand binding.^{37,52} Thus, ligand-dependent transactivation of ERs arises from ligand-induced conformational changes, which are decisive for the recruitment of coregulators. Though it has been assumed for a long time that the full-length hER and the

isolated LBD domain adopt similar conformational changes upon ligand binding, interdomain interactions are now thought to play a significant role in the recruitment of coregulators because a particular ligand may induce conformational changes that are not restricted to the LBD.⁵³ It has been previously reported that the two hERs undergo distinct conformational changes and conformational stabilities as a result of E2 and 4-OHT binding. Both ligands affect the conformation of hER α , but only E2 increases its thermal stability. Inversely, both ligands enhance the thermal stability of hER β , whereas only E2 affects its conformation.^{54,55} Our results, obtained from combined fluorescence quenching and time-resolved data, show that the flexibility of both hERs is decreased upon hormone binding regardless of the ligand used. It is observed that flexibility changes decrease in the order E2 \sim RAL \sim 4-OHT > DES for hER α and E2-4-OHT > RAL > DES for hER β . These results show that E2 and 4-OHT exert similar effects on the flexibility of both hERs and that DES is the ligand that reduces the protein conformational flexibility the most. Agonist as well as antagonist binding to full-length hERs induces conformational changes with distinct flexibilities. Protein flexibility and ligand categories (agonist, antagonist, or SERM) cannot be linked. The total interaction energies computed for E2, DES, 4-OHT, and RAL in hER α and in hER β are in total agreement with the decrease in flexibility observed experimentally. In both isotypes, DES is the best ligand as compared to others as the potential energy is the lowest (see Table 5). Structural analysis evidenced that lateral ethyl groups

Table 5. Total Potential Energies Computed for Crystal and *in Silico* Complexes^a

ligand	total potential energy (kcal mol ⁻¹)	
	rhER α	rhER β
E2	-21924	-18471
DES	-22426	-20436
4-OHT	-20935	-20374
RAL	-19429	-18639

^aThe values in italics refer to those of complexes coming from our docking studies; the others were computed from crystal complexes.

of DES involve additional binding in hER α with Trp383 of helix 5 and Phe425 and Leu540 of the NR-box. These residues, strictly conserved in hER β as Trp335, Phe377, and Leu490, respectively, reinforce the positioning of ligand and could contribute to freezing the H12 helix, which has been shown to be critical for hER α stability and flexibility (Figure 7).

Figure 7. Close view of DES in the binding pocket of hER α (left) and hER β (right). The residues that are particularly involved in the interaction with the lateral ethyl groups, shown with black arrows, are labeled sticks.

CONCLUSION

Consistent with our study and previous reports, the structural and energetic features, as determined from full-length estrogen receptors, likely constitute key factors of the fate of hERs in the cells. hER flexibility, stability, and the resulting conformational states must mediate the protein–protein and protein–DNA interactions and ultimately, by modulation of the hERs, binding status and their subcellular localization. From the thermodynamic side, the cellular signaling mechanisms may allow the system enthalpy to vanish. Finally, the relevance of *in vitro* measurements for investigating the cellular behavior of transcriptional factors is demonstrated even though linear extrapolations from *in vitro* to *in vivo* experiments might be hazardous. We propose that the distinct behaviors exhibited by the hERs, evidenced in this study, are functionally relevant for warranting their respective activities within distinct intracellular environments.
