Running title: Reproductive costs in males

Abstract

Reproduction requires resources that cannot be allocated to other functions resulting in direct reproductive costs, i.e. trade-offs between current reproduction and subsequent survival/reproduction. In wild vertebrates, direct reproductive costs have been widely described in females, but their occurrence in males remains to be explored. To fill this gap, we gathered 53 studies on 48 species testing direct reproductive costs in male vertebrates. We found a trade-off between current reproduction and subsequent performances in 29% of the species and in every taxa. As 73% of the studied species are birds, we focused on that class to investigate whether such trade-offs are associated with i) levels of paternal care, ii) polygyny or iii) pace of life. More precisely for this third question, it is expected that fast species (i.e. short lifespan, early maturity, high fecundity) pay a cost in terms of survival whereas slow species (with opposite characteristics) in terms of fecundity. Our findings tend to support this hypothesis. Finally, we pointed out the potential confounding effects that should be accounted for when investigating reproductive costs in males and strongly encourage the investigation of such costs in more taxa to understand to what extent our results are relevant for other vertebrates.

Keywords: Costs of reproduction, Generation time, Life history, Paternal care, Polygyny, Trade-off, Vertebrates

1. Introduction

Trade-offs, resulting from constraints on the evolution of linked traits, play a central role in life history theory [1]. According to the principle of allocation [2], individuals allocate their limited amount of resources to a function at the cost of other ones. Therefore, the maximum fitness an individual can reach is limited by trade-offs among fitness components. The theory about reproductive trade-offs, first formalized by Williams [3], suggested that, as reproduction is energy-demanding, individuals should trade current reproduction versus future reproduction via reduced future fecundity (i.e., fecundity costs of reproduction) and/or reduced future survival (i.e., survival costs of reproduction) [1,4]. However, as formulated by the van Noordwijk and de Jong's model [5], even if two traits compete for the same resource at the individual level, such a negative trade-off can remain undetected at the population level, because individuals can differ in both resource acquisition and resource allocation to each trait depending on the quality of their habitat or on their own quality.

Nearly 50 years after Williams's publication [3], studies investigating costs of reproduction have flourished. Stearns reviewed studies investigating the effects of reproduction on growth, parental survival, late fecundity and longevity in a wide range of taxa and with different methods, including laboratory experiments, unmanipulated and manipulated field populations [1]. More recently, studies investigating specifically direct reproductive costs in wild mammals, i.e. the co-variations between current reproduction (at time t) and subsequent reproduction and/or survival (at time $t+1$), have been reviewed [6]. Interestingly, most of the studies gathered in this review focused on females [6]. There have in fact been considerably fewer attempts to assess trade-offs among fitness components in wild males. This bias may be in part explained by methodological problems, i.e. it is often more difficult to assess reproductive effort in wild males than females [7]. Also, while it has become an accepted notion that reproduction is costly for males as well [8–10], studies dealing with costs of reproduction in males are often rooted in the theory of sexual selection and therefore refer to the cost of producing or maintaining sexual traits on future survival [8] (see [11] for a recent review on the relationship between strength of sexual selection and age-specific survival patterns across vertebrates). Investigating reproductive costs in males, specifically through the co-variations between life history traits (also called direct fitness traits sensu Roff [4], i.e. fecundity and survival) can be important because such costs that are expressed at the individual level may also have implications at the population level [12]. Thus, in the perspective of the development of more realistic population models that include both females and males, a better understanding of constraints shaping fitness traits in males appears important.

In a broad evolutionary context, theory predicts that i) the intensity of mating competition in polygynous species should translate into higher costs of reproduction for males compared to socially monogamous species [13]. At the same time, ii) species characterized with high level of paternal care are expected to be the ones with the highest reproductive costs, as parental care is energy-demanding [3,14,15]. While a high level of polygyny or paternal care is expected to be costly for males, such costs of reproduction can also strongly depend upon the position of the species on the fast-slow continuum of life history variation [16,17]. Indeed, the recent extension of the van Noordwijk and de Jong’s model [5] predicts that reproductive costs are closely linked to the position of a given species on the fast-slow continuum [6], that contrasts fast species with early maturity, high fecundity, and short lifespan, to slow species with opposite characteristics (see [18] for a recent review). Briefly, iii) fast species characterized with high variance in survival and low variance in reproduction should exhibit survival costs of reproduction, whereas slow species should rather suffer from fecundity costs. While this evolutionary model has been first supported in female mammals [6], its validity for male vertebrates remains to be investigated.

In this review, we summarize the empirical tests of reproductive trade-off between two breeding seasons in males in unmanipulated wild terrestrial and seasonally reproducing birds, mammals, squamates and amphibians (figure S1 and ESM1). We choose to focus on these taxa because most of the long-term individual based field studies, essential in this context, are done on these species [19]. Experimental approaches have been useful tools to study trade-offs and to show relationship of causality [20]. Thus, numerous studies have investigated costs of reproduction in males from experimental field populations, by assessing for instance the effect of brood size manipulation in birds (i.e., reduced or enlarged) on subsequent survival and/or reproduction (e.g. [21,22] for reviews of experimental studies). However, as we aim here to report tests of direct reproductive costs with potential demographic consequences, we focus our literature survey on males of unmanipulated wild populations. Then, we compare the occurrence of direct costs of reproduction between taxa and species. As most of the gathered studies in our review use birds as case studies, we focus on that taxon to question the link between direct costs of reproduction and i) level of polygyny, ii) level of paternal care, and iii) pace of life (i.e. the position on the fast-slow continuum). Moreover, we discuss possible biases of correlative studies in the wild with regard to identifying reproductive costs in males. Finally, we discuss the implication of our results for the other taxa of terrestrial vertebrates and suggest some future lines of research. In particular, we encourage the inclusion of trade-offs between fitness-related traits in males into demographic models of population growth to better predict the fate of wild vertebrate populations.

2. Tests of direct costs of reproduction in males

We gathered 53 studies on 48 vertebrate species investigating the co-variations between current (*t*) reproduction and subsequent (*t+1*) reproduction/survival (search protocol in ESM2, results of the literature search in table S1). It is noteworthy that the most represented class is the bird one with 35 species for which such co-variations have been investigated. We found only 7 mammalian species, 4 squamate species and 2 amphibian species. In total, we reported 116 co-variations (including one non-informative co-variation) between reproductive trait at *t* and reproduction/survival at *t+1* (tables S1 and S2, figure 1).

Because of high variability of traits considered at *t* in the reviewed studies (table S1), we summarized them into 6 types of traits namely “number of young” (e.g. when clutch size has been considered as a reproductive trait at *t*), “breeding status” (e.g. comparison of subsequent performances of breeders vs. non breeders), “mating” (e.g. number of matings), “paternal care” (e.g. a measure of feeding rate), “timing” (e.g. comparison of early vs. late breeders) and “number of breeding” (e.g. number of broods produced). In 74% of the co-variations (i.e. 85/115), the number of young produced or breeding status was used to assess reproductive effort at time *t* (table S2). The use of breeding status as a trait at *t* means that direct costs of reproduction are investigated through the comparison of subsequent performances of breeders (or successful breeders) with subsequent performances of non-breeders (or failed breeders) (table S1). Thus, negative co-variations between current reproduction and subsequent performances, i.e. when non-breeders at *t* (or failed breeders at *t*) outperformed breeders at *t* (or successful breeders at *t*) the subsequent breeding season (*t*+1), suggest the existence of direct costs of reproduction. Reproductive traits linked to the level of paternal care, the timing of breeding, the number of matings or the number of breeding may be difficult to measure in the field and are specific of the ecology/reproductive cycle of each species. That can explain why these traits are less often used in the reviewed studies (table S2). For example, in the black grouse (*Tetrao tetrix*), a lekking species for which the amount of paternal care is absent, the authors used the number of matings as a reproductive trait at time *t* [23].

Negative co-variations between reproduction at *t* and survival or reproduction at time *t+1* were detected in 29% of the reported species (table S1). Despite the low number of studies on some taxa, it seems that males of all the taxa have equal probability to exhibit direct costs of reproduction (figure 1, table S3). More precisely, these costs correspond to 16 negative co-variations between life history traits among the 115 co-variations reported (tables S1 and S2). Interestingly, even if the traits "breeding status" and "matings" have a tendency to be more frequently involved in such negative co-variations, there is no significant effect of the types of trait considered at *t* on the probability to detect reproductive costs (tables S2 and S4). Therefore, breeding (or successfully breeding) in a given breeding season may negatively affect male survival to the next breeding season (this is the case for 3 species out of 21) and may also affect reproduction (for 4 out of 15 species) (table S2). Similarly, for some species, a high number of young, of paternal care, of matings or of breeding reduces male survival or reproduction the next breeding season (table 1). Moreover, the probability to find a negative co-variation in a study does not depend on the number of co-variations tested (table S5) or the number of types of traits tested neither (table S6), suggesting that the differences in sample sizes between studies do not bias our results.

Regarding traits considered at *t+1,* 57% of the studies investigated only survival costs, 34% both survival and fecundity costs, and only 9% investigated fecundity costs alone (table S1). Interestingly, no study investigating both types of costs provided support for both. For instance, in Laysan albatross (*Phoebastria immutabilis*) or Nazca booby (*Sula granti*), male breeders (or successful breeders) can pay a cost in terms of survival to the next breeding season but not in terms of fecundity (i.e. probability to reproduce given survival) [24,25]. In king penguin (*Aptenodytes patagonicus*), Southern giant petrel (*Macronectes giganteus*) and spotted owl (*Strix occidentalis*), the effect was opposite: breeding affected future breeding probability but not survival [26–28]. Similarly, in great reed warbler (*Acrocephalus arundinaceus*), there is a cost of paternal care on future reproduction (timing of settlement) but no detectable cost on survival [29]. This stresses the importance to study both fecundity costs of reproduction and survival costs of reproduction.

3. Reproductive costs in male birds and their link with paternal care, polygyny and pace of life

For some species, negative co-variation between reproduction at time *t* and subsequent reproductive performance occurred, whereas for others species, the co-variation was null or positive (figure 1). These differences among species may be explained by differences in mating systems, levels of paternal care or pace of life resulting in different life history strategies. Indeed, we expect higher costs for males in polygynous mating systems, or when males invest more in paternal care. Moreover, as highlighted for female mammals, a close relationship between pace of life and the type of direct reproductive costs detected may be expected, i.e. fast species should be affected by survival costs of reproduction whereas slow species by fecundity costs of reproduction [6]. Generation time provides a relevant measure to rank the species on the fast-slow continuum [17]. Therefore, we expect an increase of the probability to find a fecundity cost of reproduction compared to the probability to find a survival cost of reproduction with longer generation times.

We chose to test these predictions only for male birds because 73% of the species in the reviewed studies are birds. Moreover, the different bird species gathered in this review exhibit a wide range of avian life histories along the fast-slow continuum, diverse mating systems and levels of paternal care which is essential to test these three hypotheses. More precisely, 11 studies revealed direct costs of reproduction in males (7 found survival costs and 4 fecundity costs of reproduction) among the 35 different bird species we gathered (table S1). For most species, a score of paternal care and polygyny was available from the literature [30] (see table 1 for details on score calculation) and, for each species, the generation time (in years) was retrieved from species specific demographic studies (table 1). We found that the probability to observe a cost of reproduction in one species did not depend on the level of polygyny (table S7.A) or the level of paternal care (table S7.B). Thus, with the current dataset, there is no evidence that species suffering from direct reproductive costs are the ones with the highest levels of paternal care or polygyny. However, as expected, species suffering from fecundity costs of reproduction have longer generation times than species suffering from survival costs of reproduction, except for one outlier, the Laysan albatross [25] (figure 2). This result tends to support a relationship between the pace of life and reproductive costs [6]. It remains to see from studies in other taxa whether this is a general pattern in vertebrates.

The results of these statistical comparisons should be considered with some caution. First, the power of our tests may be low due to the number of studies that include data on costs of reproduction. Second, the levels of polygyny, of paternal care and the generation times were calculated at the species level. However, it is true that some variation in these variables can exist among populations of the same species [31–33] and even among individuals within a population [e.g. for paternal care 34]. As a consequence, investigating the relationship between reproductive trade-offs and levels of paternal care, polygyny or pace of life measured at different levels of biological organization (such as at the population level) may be really interesting. It is noteworthy that in this review, we reported opposite results in terms of reproductive costs in two populations of the same species, the willow tit (*Parus montanus*). In one of them, survival costs of reproduction have been detected [35] but not in the other one [36]. Whether these two populations differ in their level of paternal care, polygyny or pace of life and whether these differences are translated into different costs of reproduction remain to be explored.

4. Negative, positive or null co-variations between current reproduction and subsequent performances and the detection of reproductive costs

We reported 14% of negative co-variations between current reproduction and subsequent performances and also 58% of null and 28% of positive co-variations (figure 1). The high proportions of null and positive co-variations may partly explain why studies dealing with reproductive costs are often oriented towards females in the literature.

A negative co-variation between current reproduction and subsequent performances may indicate that males trade their current reproduction versus their subsequent performances and thus that males suffer from direct reproductive costs [3]. However, this pattern may be more complex. In mating systems where males and females interact, the investment of one sex in a current reproductive event may depend on the characteristics of the other sex. For instance, the theory of differential allocation predicts that a mate may invest more or less in reproduction when paired with their preferred mate (or with high quality mate) [positive or negative differential allocation: 37]. This pattern can create positive or negative correlations between life history traits for males that are driven by females' investment in reproduction and that are not linked to male reproductive costs. However, because positive differential allocation seems more frequent than negative differential allocation (at least in birds [38]), it should be rare to find a negative co-variation between male life history traits in absence of real reproductive costs for males.

A null or a positive co-variation between current reproduction and subsequent performances may indicate the absence of direct reproductive costs in males. Again, interaction between the sexes may drive this pattern, for example if the absence of reproductive costs in males is correlated to the presence of such costs in females. Such correlations may depend on how strong the sexual conflict over parental investment is and how it is resolved in each species [30,39]. Therefore, it would be particularly interesting to compare both males and females in the same study. Moreover, it is noteworthy that males that do not exhibit direct reproductive costs may pay a cost later in life [40], or may suffer from other types of costs, such as inter-generational or cumulative costs of reproduction (see ESM1).

Remarkably, null or positive co-variations between current reproduction and subsequent performances may be found even if direct reproductive costs are present. First, in certain cases, individuals that try to reproduce but do not succeed to sire offspring may pay quite similar fitness costs than successful breeders. This could be more important in males than females because typically males can invest large amount of energy prior to mating (e.g. actively searching for mates, trying to defend a territory, injuries during combat) without managing to successfully sire offspring [7]. Also, brood loss may happen late in the season or, at least, after that most of the energy allocated for reproduction has already been invested in the current reproductive event. Therefore, in these cases, one will fail to detect any difference in terms of future survival and/or reproduction between breeders (or successful breeders) and non-breeders (or failed breeders) even if direct costs of reproduction occur. Second, the detection of reproductive costs may be masked by phenotypic differences in individual quality. Indeed, in case of high variance in resources acquisition, individuals able to acquire more resources (i.e. high quality individuals) are also able to allocate more resources than other individuals to both current reproduction and future survival and/or reproduction, which can prevent the detection of costs of reproduction at the population level [5]. These limitations due to individual heterogeneity explain in part why experimental studies have been widely used to study trade-offs [e.g. 22]. However, studies of unmanipulated wild populations are still essential to understand the ecological consequences of life history variations and to obtain realistic estimates of demographic parameters [19]. Thanks to the development of appropriate statistical tools, accounting for individual heterogeneity is possible, making the correlative studies more powerful [6,41]. Yet, it is likely that among the high proportion of studies that reported no negative co-variation between current reproduction and subsequent performances, some of them actually concluded to the absence of direct costs of reproduction even if they occurred in the considered species.

More generally, it is also possible that some studies may fail to detect negative co-variation between reproduction at time *t* and survival/fecundity at time *t+1*, even if there are some real costs of reproduction, because appropriate co-factors are not taken into account. For example, differences in individual quality may be more pronounced in years with harsher environmental conditions when resources are more limited, resulting in annual variations in trade-off detection [e.g. 24,42]. Accounting for age-effects may also be recommended while investigating direct reproductive costs. Indeed, reproductive performances may be age-specific, with for example lower reproductive output at old ages compared to younger ages due to senescence [43,44], or at the opposite lower reproductive output at young ages due to inexperience [45], possibly preventing the detection of reproductive costs. Carefully disentangling the age effects from the costs of previous reproduction appears crucial. Moreover, it is also important to keep in mind that the age of the individuals can mediate the trade-offs between current reproduction and subsequent reproduction and/or survival. In other words, reproductive costs themselves can be dependent on the age. For example, reproduction can be more costly in young individuals [46] or on the contrary more costly in old individuals

[47], or appear more costly due to terminal investment [48]. Therefore, studies combining the information of age effects and life history trade-offs should be developed to strengthen comparative studies and to improve our general understanding of such patterns.

Finally, in many of the studies included in the present review, it is assumed that the social and genetic father is the same. In birds for instance, the number of eggs/chicks present in the nests is used as an estimator of male reproductive success. However, thanks to molecular genetic tools, it is now accepted that, even in socially monogamous species, individuals can engage in extra-pair copulations [14,49]. In particular, males involved in such extra-pair copulations can increase their reproductive success without increasing their amount of paternal care. This means that some traits measured at time *t* may be more or less correlated to the reproductive success and the paternal investment of the males. For example, certainty of paternity has been shown to covary with paternal care in birds [50]. Thus, even if a male has a large clutch, its investment may be low if some chicks are sired by a different male. This is why the quantification of extra-pair parternity can allow more precise measurement of reproductive effort, which may allow highlighting different relationships between reproduction at time *t* and fitness-related trait at *t+1*.

5. Conclusion and perspectives

In this review, we gathered studies exploring the co-variations between current reproduction and subsequent reproduction and/or survival of wild unmanipulated terrestrial male birds, mammals, squamates and amphibians. It is noteworthy that our review reports some studies highlighting positive co-variations between life history traits, suggesting that the individual quality hypothesis is often supported in male vertebrates. But we also found empirical evidence of direct reproductive costs in several species, belonging to all taxa, even with the inherent difficulties of correlative studies. It is thus obvious that direct reproductive costs concern both males and females in wild populations.

We showed that the occurrence of reproductive costs in males is not correlated to polygyny and levels of paternal care but is associated with pace of life, in birds at least. Unfortunately, the small number of studies in the other taxa did not allow us testing our evolutionary hypotheses in other terrestrial vertebrates. However, we are confident that our results, drawn from birds, may also be relevant to other taxa. Indeed, after some evidence of a link between pace of life and costs of reproduction in female mammals [6], our review provides support for that life-history model in male birds. Yet, exploring to what extent such a model can be generalized to all terrestrial vertebrates, and, in particular, unravelling the factors that may explain variations among taxa remain an exciting challenge. For example, in line with a comparative study that has shown that birds have a slower life-history than mammals for the same body mass [51], one could expect different relationships between pace of life and costs of reproduction in males in these two taxa. Another important difference within vertebrates is the mode of temperature regulation. Indeed, ectotherms can store energy more efficiently than endotherms like birds, and thus rely more often on stored resources to fuel reproduction (capital vs. income breeders) [52]. Such different reproductive strategies may induce different reproductive costs. Thus, we strongly encourage further studies in more taxa with diverse mating systems and life history strategies to be able to broaden these results.

Correlations between life history traits and in particular, reproductive trade-offs, can have demographic consequences and can influence population dynamics [53]. It is true that most models in population dynamics are female-based and neglect males [54] but there is now growing evidence that males may markedly influence population dynamics as well (e.g. [55,56]). While methodological developments now provide the tools to integrate costs of reproduction into population models [53,57], a promising avenue of research could be to take into account reproductive costs in males as well as females into population dynamic models. Even if all models are approximations, capturing the fluctuation of demographic parameters and accounting for it into population models is the best way to provide sustainable and relevant management and conservation scenarios.

Data accessibility

87. Hannon, S. J. & Dobush, G. 1997 Pairing status of male willow ptarmigan: is polygyny costly to males? *Anim. Behav.* **53**, 369–380. (doi:10.1006/anbe.1996.0328)

Table 1. Scores of paternal care, polygyny and pace of life. Details on the bird species for which direct reproductive costs have been tested in males. We present their order and family, and their associated scores of paternal care and polygyny. These scores were calculated by Olson et al. [30]. Briefly, the method to calculate the score of paternal care consists in scoring paternal investment in 5 different activities: nest building, incubation, brooding, chick feeding, and chick defence. For each activity, the participation of males was scored on a 5-points scale: 0 (no male care),1 (1–33% male care), 2 (34–66% male care), 3 (67–99% male care) or 4 (100% male care). Thus the maximum score for each species is 20. The score of polygyny represents the percentage of males exhibiting polygyny, with: 0 (no polygyny or less than 0.1% of individuals), 1 (rare polygyny: 0.1–1%), 2 (uncommon polygyny: 1–5%), 3 (moderate polygyny: 5–20%) and 4 (common polygyny, greater than 20%). Generation time (in years), a measure ranking the species on the fast-slow continuum, was extracted from Birdlife International database (http://www.birdlife.org/datazone/home). The column "*Negative co-variation?*" indicates whether at least one negative co-variation between reproduction at *t* and fecundity ("*F*") and/or survival ("*S*") at *t+1* was found for the considered species or not ("*N*").

Figure captions

Figure 1. Distribution of the number of tested co-variations between current reproduction and subsequent performances in male terrestrial vertebrates. Number of co-variations between reproduction at time *t* and survival/reproduction at time *t+1* collected in the literature in amphibians, birds, mammals and squamates.

Figure 2. Types of direct costs of reproduction in male birds and pace of life. Differences in generation times (in years) between the bird species for which fecundity costs of reproduction (in blue) and survival costs of reproduction (in red) have been reported for at least one reproductive trait. Dots represent the data points (see table 1).
