Bacterial RuBisCO Is Required for Efficient
Bradyrhizobium/Aeschynomene Symbiosis

Abstract

Rhizobia and legume plants establish symbiotic associations resulting in the formation of organs specialized in nitrogen fixation. In such organs, termed nodules, bacteria differentiate into bacteroids which convert atmospheric nitrogen and supply the plant with organic nitrogen. As a counterpart, bacteroids receive carbon substrates from the plant. This rather simple model of metabolite exchange underlies symbiosis but does not describe the complexity of bacteroids’ central metabolism. A previous study using the tropical symbiotic model Aeschynomene indica/photosynthetic Bradyrhizobium sp. ORS278 suggested a role of the bacterial Calvin cycle during the symbiotic process. Herein we investigated the role of two RuBisCO gene clusters of Bradyrhizobium sp. ORS278 during symbiosis. Using gene reporter fusion strains, we showed that cbbL1 but not the paralogous cbbL2 is expressed during symbiosis. Congruently, CbbL1 was detected in bacteroids by proteome analysis. The importance of CbbL1 for symbiotic nitrogen fixation was proven by a reverse genetic approach. Interestingly, despite its symbiotic nitrogen fixation defect, the cbbL1 mutant was not affected in nitrogen fixation activity under free living state. This study demonstrates a critical role for bacterial RuBisCO during a rhizobia/legume symbiotic interaction.

Introduction

The Calvin Benson Bassham cycle (CBB cycle), also termed reductive pentose phosphate pathway, is the quantitatively most important mechanism of autotrophic CO2 fixation in nature [1]. Its key enzyme ribulose 1,5 bis-phosphate Carboxylase Oxygenase, RuBisCO catalyzes the formation of two molecules of 3 phosphoglycerate from ribulose bisphosphate and CO2 and has been subjected to extensive studies since its discovery [2]. Besides fundamental interest in carbon assimilation, research in this field is also motivated by the objective to improve crop yield and by the capacity of CO2 assimilation. The phenomenon of substantial CO2 assimilation by the cell. The phenomenon of substantial carbon fixation in the presence of multicarbon compounds was observed earlier and an alternative role of the CBB cycle in some microorganisms suggested that consists in redox cofactor balancing [3,6,7,8,9].

Sinorhizobium meliloti, Bradyrhizobium japonicum and the photosynthetic Bradyrhizobium strain BT-31 are known to assimilate CO2 via the CBB cycle [10,11,12]. These microorganisms belong to the polyphyletic rhizobial group. Rhizobia are soil bacteria able to form symbiotic interactions with legume plants. During these symbiotic interactions, plants develop new organs on their root system. In these organs, termed nodules, bacteria reside intracellularly and their metabolism is drastically modified as it is largely dedicated to the reduction of atmospheric nitrogen that is made available to the plant host. In return bacteria receive organic carbon in the form of dicarboxylic acids from the plant. This basic assimilation carbon versus nitrogen exchange is the basis of the symbiotic relationship between both partners [13] but the metabolites exchanges seems much more complex [14].

Photosynthetic bradyrhizobia induce and colonize nodules on semi-aquatic legume plants belonging to the Aeschynomene genus [15]. Beyond their photosynthetic trait, bacteria involved in these interactions present other atypical aspects compared to classical rhizobia. They can fix nitrogen in the free living state, an ability restricted among rhizobia to photosynthetic bradyrhizobia and to Azorhizobium caulinodans [16,17]. Furthermore, photosynthetic bradyrhizobia lack the nodABC genes, indicating that these bacteria interact with their legume host according to a new molecular mechanism independent of the long-time considered universal
Nod factors [18]. Finally, in accordance with the semi-aquatic nature of their Aeschynomene host, they distinguish from classical rhizobia by their adaptation to the aquatic environment beyond the classical rhizobial habitats (rhizo-, phyllo-sphere, soil and root nodules). As a consequence, photosynthetic bradyrhizobia nodulate not only the roots but also the stems of Aeschynomene plants when the latter are subjected to immersion. This capacity to colonize various environments (stem and root nodules, plant surfaces, soil, and flooded area) might rely on versatile metabolic skills. As an example, photosynthetic capacities of the model Bradyrhizobium sp. ORS278 were shown to be important for stem nodulation but not root nodulation [19].

In a previous study aiming at identifying ORS278 mutants altered in the symbiotic process, four Tn5 insertional mutants potentially affected in the CBB cycle were described as altered in their symbiotic nitrogen fixation capacity (Fix- phenotype) [20]. ORS278 genome harbours two RuBisCO gene clusters [18] encoding for proteins which belong to the form I RuBisCO of heterodimeric proteins containing 8 large and 8 small subunits. (Figure 1). The existence of two RuBisCO genes, both associated with a regulator, suggests that ORS278 might differentially use one or the other enzyme depending on environmental conditions. Herein we investigated the importance of RuBisCO 1 and 2 during the symbiotic process and demonstrate the contribution of RuBisCO 1 to symbiosis.

**Results**

**Bradyrhizobium spp. ORS278 genome houses two physically and phylogenetically distant RuBisCO gene clusters**

As mentioned above, the two predicted ORS278 CbbL proteins belong to the group of Type I RuBisCO enzymes, nevertheless they exhibit a sequence identity of only 57%. Neighbour joining analysis performed on various procaryotic Rhizobium large subunit sequences showed that the two ORS278 genes belong to two distinct clades (Figure 2). RuBisCO 1 belongs to the IC Rhizobium class, a group related to medium to high CO2 environments [23]. Beyond the CbbL1 closest ortholog in BTAi1 (99% of identity), predicted proteins are well conserved in some non-photosynthetic rhizobia such as Sinorhizobium meliloti with an identity level of 76% [24] or B. japonicum (91% identity). In these three strains, the genomic context is well conserved and the whole gene clusters exhibit a perfect microsynthy (Figure 1). A CbbL1 homologue (76% of identity) is also present in the phylogenetically distant beta-rhizobium Cupriavidus taiwanensis [25]. RuBisCO 2 belongs to the IAc Rhizobium class, which harbors orthologs from other Alphaproteobacteria such as Nitrobacter strains, Beta- and Gammaproteobacteria as well as Cyanobacteria, this class is related to low CO2 environments [23]. The only known rhizobial ortholog in the IAc clade is Bradyrhizobium sp. BTAi1 (>99% of identity).

Only \textit{cbbL1} is expressed in planta

In order to determine any potential contribution of RuBisCO 1 or 2 during the symbiotic process, reporter strains carrying \textit{gus} fusion downstream of the predicted promoter region of the RuBisCO gene clusters were constructed. \textit{A. indica} nodules of different age induced by these strains (5, 7, 10, 14, 21 days post-inoculation) were sliced into thin layers, stained with X-Gluc and reporter gene expression was monitored by standard light microscopy. No detectable activity of \textit{gus} reporter fusion was revealed for the \textit{cbbL2} promoter region. In contrast, the 5' region of the \textit{cbbL1} gene cluster displayed a transcriptional activity detectable at every stages of nodule development examined even at five dpi when first young nodules appeared. This expression did not seem to diminish in mature nodules (Figure 3A corresponds to 14 dpi nodule). In order to determine if CbbL1 protein is produced in nodules, a proteomics analysis was performed on bacteroids isolated from \textit{A. indica} 14 dpi nodules. Protein extract was separated by SDS-PAGE and a gel section corresponding to

\caption{Evolutionary relationships of RuBisCO large subunit sequences. Neighbour joining method was used. Bootstrap support values (10000 replicates with Mega4) are provided as percentage at the corresponding nodes. CbbL1 and CbbL2 proteins from ORS278 strain are highlighted in bold characters. For RuBisCO IA members, the RuBisCO subclasses IAc and IAq is indicated before bacterial name. doi:10.1371/journal.pone.0021900.g002}
\end{figure}
CbbL1 and 2 predicted molecular weight was analysed by trypsin digestion followed by LC-MS/MS. Fragmentation profiles allowed the identification of four peptides from CbbL1 (Figure 4) but none of CbbL2.

cbbL1 is required for efficient symbiotic nitrogen fixation

In order to evaluate the importance of RuBisCO 1 or 2 during the symbiotic process, mutant strains harbouring a deletion in one of the two genes coding for the large RuBisCO subunit CbbL1 were constructed and inoculated on A. indica. To prevent any effect of bacterial photosynthesis and mimic natural conditions, plants were root inoculated and roots systems were maintained in the darkness. Two weeks after inoculation, acetylene reduction assays were conducted to evaluate nitrogenase activity of plants housing the different strains. Whereas no significant defect was observed for plants inoculated with the cbbL2 mutant, plants inoculated with the cbbL1 mutants exhibited a nitrogenase activity defect ranging from 30 to 50% to that of the wild type (WT) strain (Figure 5A). This result was consistent with phenotypic observations of three week old plants which revealed that plants inoculated with a cbbL1 mutant but not those inoculated with a cbbL2 mutant exhibited typical nitrogen starvation symptoms such as foliage chlorosis or stem thinning (Figure 3B). Symptom intensity did not reach those observed on plants inoculated with a nifK mutant which was altered in the nitrogenase enzyme itself and therefore displayed a strict Fix− phenotype.

The cbbL1 mutant induces more nodules which are heterogenic in phenotype

Root systems of plants inoculated with the cbbL1 mutant harboured two times more nodules than those inoculated with the WT strain (Figure 5B) and was thus in the same range as observed upon inoculation of a nifK mutant. On every root system, cbbL1 induced more than 80% of nodules with a yellow colour typically indicative of nitrogen fixation deficiency, the remaining being WT-like reddish nodules (Figure 3C, 5B). In order to determine if a secondary mutation occurred in cbbL1 mutants present in WT-like nodules, bacteria were rescued from these nodules. After cultivation, mutation in cbbL1 was confirmed by PCR and these cbbL1 mutants derived from WT-like nodules were inoculated on new plants. The resulting root systems displayed also a mixture of WT-like and yellowish nodules. This result demonstrated the heritable nature of the heterogenic phenotype and excluded the possibility of secondary mutations in cbbL1 mutants forming WT-like nodules.

cbbL1 is not required for in vitro nitrogen fixation

In order to determine whether the symbiotic defect observed with the cbbL1 mutant was directly related to nitrogen fixation capacity, we investigated the bacterial capacity to fix nitrogen under free-living conditions. Using succinate, malate or 2-oxoglutarate as a sole source of carbon and energy, no significant nitrogenase activity defect was revealed by acetylene reduction assays (Figure 5C and not shown) demonstrating the absence of direct correlation between the presence of RuBisCO 1 and the capacity to fix nitrogen.

Discussion

The presence of an active RuBisCO has been reported in several rhizobial strains including photosynthetic and non-photosynthetic rhizobium; however, to our knowledge, so far no role of this enzyme during the symbiotic process has been reported. In this study, we demonstrate that one of the two
RuBisCO enzymes identified in the photosynthetic *Bradyrhizobium* strain (ORS278) is required for an efficient symbiosis with *A. indica* plants. First, we showed expression of the *cbbL1* but not *cbbL2* gene during the symbiotic process and second, we observed a reduced symbiotic nitrogenase activity level of plants inoculated with *cbbL1* mutant leading to typical nitrogen starvation symptoms such as foliage chlorosis and stem thinning. *cbbL1* interacting plants display nitrogen starvation symptoms weaker than plants housing nitrogenase minus mutants. This intermediary phenotype can be explained by the heterogeneity of the induced nodules. Indeed, *cbbL1* induced a mixture of WT-like, reddish, and fix minus-like, yellowish, nodules on the same plants. Yellowish nodules are likely nitrogen fixation deficient whereas the WT-like nodules probably fix and transfer nitrogen to the host, partially compensating nitrogen deprivation. This heterogeneous phenotype and *cbbL1* mutant capacity to fix nitrogen in *vitro* indicate that *cbbL1* is not essential for nitrogen fixation. Thus, the importance of RuBisCO 1 during the symbiotic process is probably not related to mature bacteroid metabolism but to an early step of the symbiosis.

Results presented here were obtained with plant root systems maintained in the darkness. Under this condition bacteria produce energy by oxidation of reduced carbon compounds supplied by the plant. In this context, the operation of the CBB cycle as a mean to produce biomass seems futile since reduced carbon is provided by the

In some photosynthetic bacteria, the CBB cycle plays an essential role during growth on reduced carbon substrates in the absence of oxygen [7,26]. In these bacteria, the CBB cycle acts as an electron sink driving the cell electron excess to CO₂ and thus oxidizing reduced cofactor and contributing in a significant way to equilibrate the redox state of the cell [6]. Interestingly, in *Rhodospirillum rubrum* and *Rhodobacter sphaeroides*, a RuBisCO mutant which is unable to grow phototrophically, can be rescued by acquiring secondary mutation derepressing nitrogen fixation genes [27]. Joshi and Tabita (1996) and more recently McKinley and Harwood (2010) explained these observations by the high reductant requirement of nitrogenase which, like the Calvin cycle, can play an electron sink role. We propose ORS278 strain uses the Calvin cycle for this purpose at an early stage of the symbiotic process: when oxygen concentration in the nodule has dropped, the Calvin cycle drives the electron excess to CO₂. Once nitrogenase synthesis has started, electron excess is consumed by the nitrogen fixation process, allowing normal nodule development. For a cbbL1 mutant leading to a Fix–like nodule: electron excess cannot be drive to CO₂, therefore, reduced cofactors accumulate and disturbed bacterial metabolism preventing normal nodule development.

**Figure 6. Hypothetical model of ORS278 central metabolism during the symbiotic process.** Upper part of the figure represents the WT and WT-like situation: Plant supplied organic carbon to bacteria which use it via the tricarboxylic acid cycle (TCA) resulting in the production of reduced cofactors (Red Cof). Reduced cofactors are totally oxidized by the respiratory chain at the early stage of nodule formation, then oxygen concentration drops and Calvin cycle drives the electron excess to CO₂. Once nitrogenase synthesis has started, electron excess is consumed by the nitrogen fixation process. Lower part of the figure represents the situation with a cbbL1 mutant leading to a Fix–like nodule: electron excess cannot be drive to CO₂, therefore, reduced cofactors accumulate and disturbed bacterial metabolism preventing normal nodule development.
already significantly decreased and before the establishment of functional nitrogenase. At such a step, reduced cofactors pool produced primarily by the Krebs cycle might not be balanced and the CBB cycle might fulfill this function, which, in developed bacteroids, is fulfilled by nitrogenase activity (Figure 6). The dynamical dimension of this hypothetical model offers an explanation to the observed WT-like nitrogenase activity (Figure 6). The dynamical dimension of this model might fulfill this function which, in developed bacteroids, is fulfilled by the Krebs cycle.

More work will be required to identify a role for RuBisCO 2 as the *cbbL2* mutant did not display any phenotype during the symbiotic process or nitrogen fixation in *vitro*. Transcriptional activity from *cbbL2* promoter was not detected during growth on rich or minimal medium using various carbon compounds. It is possible that ORS278 strain uses this enzyme under yet unidentified environmental conditions or that this cluster is not yet functional in this host strain due to its recent acquisition.

### Materials and Methods

#### Phylogenetic Analysis

RuBisCO large sub-unit sequences from various bacteria (such as *Rhodospirillum rubrum*, *Synechococcus* sp. PCC 7002, *Escherichia coli*, and *Bradyrhizobium* sp. ORS278) were aligned using the ClustalW multiple alignment [28] with a bootstrap of 10000 replicates. Resulting fragments were cloned in pGEMT easy and transformed in thermocompetent XL2-Blue. Brado2274 and Brado1659 DNA fragments were excised from pGEMT using ApaI/SpeI and NotI respectively and cloned into pH200uc1 [31] (Brado 1659) and pH200uk [31] (Brado 2274) opened with NotI and ApaI/SpeI respectively in phBG1659 and phBG2274. Ligation products were transformed into XL2-Blue cells. Once check by restriction profiles, resulting plasmids were digested with XhoI/Sall. Plasmids were transferred in *E. coli* S17-1 [33] by electroporation prior to mating with ORS278. Transconjugants were selected using nalidixic acid and kanamycin. Then transconjugants were replicated on sucrose medium containing kanamycin. Resulting colonies were check by PCR amplification of cassette flanking regions.

#### Phycobilisome Role during Symbiosis

Nitrogenase activity from *cbbL2* promoter regions was PCR amplified using Brado1655PromF/Brado1655PromR (5' -TCTAGACGT-GTCCGACACATTGCTGTGCT-3') and Brado1655PromR (5'-GGTGTCAGATGTACCATCGGATGTTG-3') and Brado2274PromF/Brado2274PromR (5'-GAAGTCGACCTGATTGTGAGTT-3') were used to amplify the central part of *cbbL2* open reading frame. DNA fragment was cloned into pGEMT easy and ligation product was transformed into XL2-Blue. After verification, insert was excise using Sall/XbaI and cloned into SalI/Sall linearised pVO155 [34]. Resulting plasmid was successively transferred into XL1-Blue and S17-1. Resulting S17-1 strain was used to introduce the construction in ORS278 by mating.

Reporter strains: putative *cbbL1* and *cbbL2* promoter regions were PCR amplified using Brado1655PromF/Brado1655PromR (5'-CATGATGATGTGGCGATGTTG-3' and 5'-GGTGTCAGATGTACCATCGGATGTTG-3') and Brado2274PromF/Brado2274PromR (5'-GAAGTCGACCTGATTGTGAGTT-3') primer pairs. DNA fragments were cloned in pGEMT easy resulting in PcbbL1-pGEMT and PcbbL2-pGEMT. SalI/XbaI insert were then excised, purified and ligated in pVO153 suicide vector [34] linearised with Sall/XbaI. Ligation products were introduced in XL2-Blue and S17-1 successively and finally transferred to ORS278 by mating.

#### Plant cultivations and inoculation

*Arabidopsis thaliana* seeds were surface sterilized by immersion in sulphuric acid under shaking during 45 minutes. Seeds were then washed with sterile distilled water and incubated overnight in sterile water. Seeds were then transferred for two days at 37°C in the darkness on 0.8% agar plate for germination. Plantlets were then transferred on the top of test tubes covered by aluminum paper for hydroponic culture in buffered nodulation medium (BNM) [35]. Plants were grown in closed mini green house in a 16-h light and 8-h dark regime and 70% humidity. Seven days after transfer, each seedling was inoculated with one milliliter of cell suspension resulting from a 5-70% humidity. Seven days after transfer, each seedling was inoculated with one milliliter of cell suspension resulting from a 5-day-old bacterial culture washed in BNM and adjusted to reach an optical density of one at 600 nm.

#### Histochemical analysis and microscopy

30-to 40-μm-thick vibratome (VT1000S; Leica, Nanterre, France) sections from fresh nodule samples were observed under bright-field illumination with an optical microscope (PROVIS; Olympus, Rungis, France). To follow glucuronidase activity,
nodule thick sections were incubated at 37°C in the darkness in a 
GUS assay buffer for 4 hours. This reaction buffer was described
in [36] and contained 0.075% (wt/vol) of X-Gluc (5-bromo-4-
chloro-3-indolyl-α-D-glucuronide) in 0.1 M K/Na phosphate
buffer (pH 7.0), 20 mM NaEDTA, 0.02% Triton X-100, 1 mM
K-ferricyanide, and 1 mM K-ferrocyanide.

Proteomics analysis
21 days post inoculation nodules were harvested and immedi-
ately flash frozen in liquid nitrogen. Bacteroids were isolated on a
sucrose density gradient using a procedure derived from [37] using
modifications described in [38] and [39]. Proteins were separated
and analysed as described in [40].

Acetylene reduction assays
In planta acetylene reduction assays were conducted as described in
[20] with minor modifications. Briefly: one plant was placed
into 125 mL glass vials sealed with rubber septa. To avoid
overpressure, 12.5 ml of air were removed before injecting the
same volume of acetylene. After 3 hours of incubation at room
temperature, the ethylene produced was measured by GC-FID
using one ml of sampled gas. At least ten plants were used per
condition. Plants inoculated with ORS278 strain were used as a
reference. In vivo acetylene reduction assays were performed as
described in [16].
