Abstract

Fungal pathogens are among the most virulent bioaggressors of protected crops. For sustainable plant production and to protect the crop against these airborne organisms one must determine their origin, i.e. whether they come from outside the greenhouse or are produced inside it.

We considered *Botrytis cinerea* spore concentration as a particular physical species which is transported by air in the same way as heat, CO₂, water vapour or any tracer gas. We constructed a mass balance of the viable *Botrytis* spores on the whole greenhouse volume to assess the inside production of spores and their exchanges.

The different elements in the spore balance are considered and are determined experimentally:

- spore transfer into or out of the greenhouse is deduced from the difference between the inside and outside spore concentrations, measured by spore traps, multiplied by the whole-greenhouse ventilation rate;
- spore deposition on soil and crop and spore impaction on the plants is deduced from observations made using Petri dishes;
- inside spore production is the differential term deduced from the whole-greenhouse volume balance.

The first measurements and calculations have shown that the presence of insect-proof nets across the greenhouse openings strongly influences the spore balance, as the nets intercept the *Botrytis cinerea* spores proportionally to the nets' solidity. Based on wind tunnel experiments, the interception capacity of the nets was quantified and the whole model completed in consequence.

These results show the diurnal *Botrytis* spore balance over 3 - 4 week periods in the autumn and spring season for a young rose plantation. In agreement with visual observations

of *Botrytis cinerea* sporulation within the greenhouse, it is shown that the origin of the inocula is predominantly internal (2/3 in quantity). However, due to outside climate and greenhouse opening, it can vary widely from one period to another, with a tendency to become predominantly internal as the crop ages.

Keywords: greenhouse, air exchange rate, spore, balance, *Botrytis cinerea*, ventilation, rose crop

1-Introduction

While biological control agents for most insect pests of greenhouse crops have been successfully applied to greenhouse crops in recent years, biological control of diseases is much less developed. Recent studies on the toxicological impact of greenhouse products (Anton *et al.*, 2004) show that disease management still largely relies on chemicals. Most airborne fungal pathogens, particularly grey mould caused by *Botrytis cinerea*, are considered a major problem for greenhouse crop production.

Microclimatic parameters have long been recognised as key factors in the spread of fungal diseases and for greenhouse climate management for disease control. For example, open vents coupled with heating that renew the air and evacuate excess water vapour released by crop transpiration inside the greenhouse; greenhouses are an efficient way of controlling pests (Nicot and Baille, 1996; Jewett and Jarvis, 2001; Tantau and Lange, 2003; Körner and Challa, 2003).

However, while the prevailing climatic conditions are crucial for fungal development, it is also very important to control the level of fungal inocula. This aspect is generally poorly known and documented. To protect crops efficiently from airborne fungal spores, the origin of the inocula must be known – i.e. whether the spores come from outside the greenhouse or have been produced inside – and also their rate of production.

We have therefore adapted a classical physical method which has hitherto been chiefly used for performing mass or heat balances in finite volumes such as buildings and greenhouses, to perform a *Botrytis cinerea* spore balance of the protected crop and determine the origins of the inocula.

In this paper we present the study designed to perform this determination, and its experimental application to a real-scale rose greenhouse in the South of France, near Nice.

2-Theory

Botrytis cinerea spore concentration can be regarded as a particular physical species which is transported by air in the same way as heat, carbon dioxide or water vapour concentration. It can also be compared to any tracer gas, such as N₂O, which is traditionally used for measuring large-scale greenhouse air exchange rates (Boulard & Draoui, 1995).

2-1- Whole-greenhouse spore mass balance

The tracer gas techniques used to measure ventilation flow rates are based on the mass balance of natural or artificial constituents of the whole-greenhouse air. For performing a greenhouse air mass balance, the choice of tracer gas is important: the gas should be inert, non-toxic and non-flammable, with a molecular weight close to the average weight of air components, and easy to measure at low concentrations. Many gases have been used, including SF₆, CH₄, CO₂, H₂, N₂O, Argon 41 and Krypton 85. The two most frequently used for greenhouses are CO₂ and N₂O, the latter being influenced neither by photosynthesis nor by plant respiration. However, water vapour (H₂O) has also been used as a “natural” tracer gas (Demrati *et al.*, 2001). Sherman (1990) has analysed tracer gas techniques for measuring ventilation in a single zone such as a greenhouse; he has shown that mixing problems can present a major source of potential error because the tracer gas must be uniformly mixed throughout the greenhouse. In these conditions Ducarme *et al.* (1994) estimate that the accuracy of an analysis by tracer gas is about 30% and that additional errors can also be caused by exfiltration air re-entering the measurement space at another location, or by changes in external conditions (wind speed, air temperature) during the measurement process.

Based on these approaches, we considered the finite volume of the greenhouse and performed its *Botrytis cinerea* spore balance according to equation (1), derived from the mass balance of the constituents of the whole-greenhouse air (Roy *et al.*, 2002):

$$V \frac{dc_{in}}{dt} = -G(t)(c_{in}(t) - c_{out}(t)) - D_{in}(t) + P_{in}(t) \quad (1)$$

where G is the ventilation flow rate, V the greenhouse volume, t the time, $c_{in}(t)$ and $c_{out}(t)$ the inside and outside concentrations of *Botrytis cinerea* spore's, $P_{in}(t)$ (sp s⁻¹) is the spore's production rate inside and $D_{in}(t)$ (sp s⁻¹) the inside spore deposition by sedimentation and impaction. One can assess the inside production of inocula $P_{in}(t)$, measuring the inside and outside spore concentrations $c_{in}(t)$ and $c_{out}(t)$ (sp m⁻³) together with the greenhouse air exchange rate $G(t)$ (m³ s⁻¹), greenhouse volume V (m³), and spore deposition on crop and soil $D_{in}(t)$ (sp s⁻¹):

In this equation we make two crucial assumptions, (i) that the variables used in equation (1) (i.e. $c_{in}(t)$, $c_{out}(t)$, G , D_{in} and P_{in}) are discrete values corresponding to the mean of the considered variable which vary from one time step to another and (ii) that all spores deposited on the surfaces of soil or leaves remain there and do not return to the air.

Integrating equation (1) on time scale ($t-\Delta t$ to t) enables us to present this equation in a continuous and recursive form (2):

$$c_{in}(t) = c_{in}(t-\Delta t) e^{-G(t)\Delta t/V} + c_{out}(t)(1 - e^{-G(t)\Delta t/V}) + ((P_{in}(t) - D_{in}(t))/G(t))(1 - e^{-G(t)\Delta t/V}) \quad (2)$$

As the time scale, Δt , for experimental spore counting is long (from 8h to 24h) the numerical value of $e^{-G(t)\Delta t/V}$ attached to the capacitive effect in equation (2) tends to 0 and becomes very small in relation to the other terms. Equation (2) then simplifies into equation (3):

$$G(t) (c_{in}(t) - c_{out}(t)) - D_{in}(t) + P_{in}(t) = 0 \quad (3)$$

Considering this equation and determining, for any time scale Δt between 8 and 24 hours, the inside and outside spore concentrations $c_{in}(t)$ and $c_{out}(t)$ together with spore deposition $D_{in}(t)$, and determining the air exchange rate $G(t)$ by means of a general ventilation model, we can deduce the rate of inside spore production $P_{in}(t)$ for the period in question. A detailed diagram of the method is presented in Fig. 1.

However, *Botrytis* spores are solid particles with an average 10 μm diameter, and can be intercepted by the solid matrix, i.e. the wires of the insect proof nets deployed on all the greenhouse vent openings, according to an equation which will be presented in section (4). The spore balance (equation (3)) must be modified in consequence to take into account a dimensionless spore interception value, F (-):

$$FG(t)(c_{in}(t) - c_{out}(t)) - D_{in}(t) + P_{in}(t) = 0 \quad (4)$$

3-Experimental setup

The experiments were carried out (Fig. 2) in three-spans of a four-span compartmented plastic greenhouse (Multclair 9600, Filclair, France). The main compartment (576 m²) was

occupied by a soilless rose plantation (3240 rose plants, cv Magnum, Milva, Suella) planted in spring (May 2003) in a new greenhouse erected just before, from December to March 2003. *Botrytis* spore balances were systematically constructed in spring and autumn, for 2 to 4 weeks each time, from 2003 to 2005 (April 2003, October 2003, April 2004, November 2004 and May 2005), the first spore balance (April 2003) being performed before the rose crop was planted and all the others after.

In the greenhouse, natural ventilation was provided by means of roof vents and a side opening, both equipped with insect-proof nets (anti-*Bemisia* 10x20 meshes/cm, with a 0.2 mm thread diameter and 0.52 mesh solidity).

3-1-Physical measurements

The main exchange parameter G was experimentally determined with the help of a general ventilation model given by equation (5), which considers both wind and stack effects together with the resistance of the insect-proof nets (which unfold on opening the vents) to air penetration (Boulard and Baille, 1995):

$$G = A_l ((S_o + S_f)/2)(2gH_c/4|T_{out} - T_{in}|/(T_{out} + 273) + C_w V^2)^{0.5} \quad (5)$$

where A_l (-) is the overall discharge coefficient of the vent and insect-proof net, C_w (-) is a wind effect coefficient on ventilation, S_o and S_f (m²) are vent opening area and the corresponding leakage area, H_c (m) is an equivalent chimney height, T_{in} and T_{out} (°C) are inside and outside temperatures, and V (m s⁻¹) is wind speed.

Wind speed and direction together with inside and outside temperature and humidity and vent opening (Fig. 3) area were systematically measured using the sensors of the greenhouse climate computer (L'ien, Vitrolles, 13, France) at a 1-minute frequency, stored and processed for a minimum average time of 15 minutes.

The model parameters A_l and C_w together with leakage area S_f , were determined in situ for this greenhouse by fitting the ventilation model to exchange rate measurements taken with tracer gas techniques, using N₂O as tracer gas (Roy *et al.*, 2002). A detailed description of the experimental study conducted to determine these parameters on this greenhouse can be found in Fatnassi *et al.* (2006) and more generally a survey of the values found in the literature can be found in Roy *et al.* (2002).

Knowing the specific greenhouse ventilation parameters A_l , C_w and S_f for the two main wind directions observed on the site and continuously measuring the inside and outside air temperatures T_{in} and T_{out} together with wind speed V and vent opening area S_o , one can easily

deduce the air exchange rate G from equation (5). In the April 2004 trial, additional inside air speed measurements for studying the determinism of spores' terminal velocity were performed, using omni-directional anemometers.

3-2-Biological measurements:

Inside (c_{in}) and outside (c_{out}) *Botrytis cinerea* spore concentrations were measured by means of two spore trap systems (Burkard Manufacturing Co Ltd, Rickmansworth, GB) with a $0.6 \text{ m}^3 \text{ h}^{-1}$ flow rate, set up inside the greenhouse about 0.5 m above the crop canopy and outside, approximately 10 m away from the greenhouse. These spore traps were used continuously during the trials.

The total spore deposit in the greenhouse (D_i) was estimated by means of 16 Petri dishes ($\varnothing 9.5 \text{ cm}$ for a surface of $71 \cdot 10^{-4} \text{ m}^2$) placed horizontally above the rose bushes ($\approx 2 \text{ m}$) to measure spore sedimentation on the crop canopy, together with 20 vertical Petri dishes oriented in the 4 cardinal directions to measure vertical impaction. Figure (3) shows schematically the horizontal position of the various biological and climate measurements inside and outside the greenhouse. The *Botrytis* spores captured from the air by the spore traps and Petri dishes were placed each day on a selective medium (Kerssies, 1990), incubated for 10 days and counted using a binocular microscope.

For comparing this indirect assessment of *Botrytis cinerea* sporulation inside the greenhouse with visual inspection, qualitative observation of *Botrytis cinerea* symptoms on rose buds and flowers and search for sporulating sources in the greenhouse were performed systematically on a weekly basis by the pathologists in charge of the experiment for all plants from 2003 to 2005.

3-3- Spore interception by the insect-proof net

Spore interception by the insect-proof net was experimentally determined by wind tunnel experiments (Fig. 4). Spore interception by the insect-proof net was regarded as the ratio of the intercepted spores to the total number of spores injected into the wind tunnel:

$$F = \text{number of spore's intercepted by the net} / \text{number of spore's injected in the vein of the wind tunnel} \quad (6)$$

The intercepted spore value (number of spores intercepted by the insect-proof net) was deduced from the measurements performed in the wind tunnel experiment, as follows:

$$\begin{aligned} \text{Number of spores intercepted by the net} &= \text{Number of spores upstream from the net} - \\ &(\text{Number of spores downstream from the net} + \text{Number of spores having sedimented in the} \\ &\text{wind tunnel}) \end{aligned} \quad (7)$$

where the number of spores upstream and downstream from the insect-proof net was measured using spore trap systems (Burkard Manufacturing Co Ltd, Rickmansworth, GB), and the number of sedimented spores was determined by means of Petri dishes. These values were deduced from the mean of 3 wind tunnel tests lasting about 2 hours and performed with an air speed of 1.5 m s^{-1} .

4-Results and discussion

Greenhouse spore balance and analysis of the principle spore characteristics are based on data recorded in 5 trials lasting between 3 and 4 weeks in April 2003, October 2003, April and November 2004 and May 2005, on a diurnal (12h from 08:00 to 20:00) and nocturnal (12h from 20:00 to 08:00) and on a 24-hour basis (from 08:00 to 08:00).

4-1- Determination of *Botrytis* spores' terminal velocity in greenhouse conditions

Although the determination of the spores' terminal fall velocity v_t , is not essential for performing their balance, the experimental results were also exploited for deducing this value which gives interesting insights on the dynamics of inside spores' transfer.

Theoretically, in still air, all suspended spores fall with a constant and characteristic terminal fall velocity v_t , given by Stokes' law (Seinfeld & Pandis, 1998) and depending on gravity g , spore radius r_p , density ρ_p , a slip correction factor C_c and air viscosity μ ($1.72 \cdot 10^{-4} \text{ g cm}^{-1} \text{ s}^{-1}$):

$$v_t = ((2r_p)^2 \rho_p g C_c) / 18 \mu \quad (8)$$

For an average *Botrytis cinerea* spore radius $r_p = 5 \text{ }\mu\text{m}$ and density $\rho_p = 1.1 \text{ g cm}^{-3}$, one obtains $v_t = 0.00368 \text{ m s}^{-1}$.

This theoretical value must be compared with the experimental determination derived from a dimensional analysis indicating that the terminal velocity of *Botrytis* spores (m s^{-1}) results from the ratio of inside spore deposition D_i ($\text{sp m}^{-2} \text{ s}^{-1}$) to inside spore concentration C_i (sp m^{-3}). In the experiments, D_i was measured by means of the horizontal Petri dishes and C_i by the Burkard spore traps, as described above.

$$v_t = D_i / C_i \quad (9)$$

For one month in April 2004 (days 104 to 134) one finds an average terminal velocity of 0.341 cm s⁻¹ with a standard deviation of 0.11 cm s⁻¹. This value is close to the theoretical value of 0.368 cm s⁻¹ deduced from Stokes' law (equation 8) for the average *Botrytis cinerea* spore diameter and density given above. This value is also within the range [0.22 to 0.45 cm s⁻¹] experimentally determined by Gregory (1973) for *Botrytis cinerea* spores.

Taking account of the dependency of the spores' terminal velocity (determined using equation 9 on a 12-hour time basis) on the inside air speed (measured by means of an omnidirectional anemometer) suggests that an increase in inside air speed tends to accelerate horizontal spore deposition (Fig. 5). As the mean inside air speed is also directly proportional to the overall greenhouse air exchange rate (Wang *et al.*, 1999), it follows that increasing ventilation tends to accelerate spore deposition as it is verified by the experimental results of Fig. 8. However, one cannot conclude if the acceleration of spore deposition is due to an aerodynamic effect or simply to the greater exchange from outside to inside.

4-2- Spore balance calculations

Spore interception by the insect-proof net

Using the wind tunnel we were able to determine an average value for spore interception by our insect-proof net of $F=0.57$. This value is very close to the nets' mesh solidity (i.e. 0.52) and suggests that, as a first approximation, spore interception is directly proportional to the solidity of the net. However, this experimental value can also be compared with an empirical expression of F calculated by Aylor and Ferrandino (1985) and pertaining to cylinders and ribbons, the threads of the insect-proof nets being regarded as cylinders:

$$F = 0.86 / (1 + 0.442 S_t^{-1.967}) \quad (10)$$

With $S_t = 2.085$, the Stokes number of the *Botrytis* spores computed for a 10 µm spore diameter (Jarvis, 1977) and an average thread Ø of 200 µm for the insect-proof net, one finds $F = 0.78$. Although this value is higher than the experimental one (0.57), the two values are not contradictory because the calculated value (0.78) assumes that all intercepted spores

remain on the net threads, whereas the measured value takes into account only those intercepted spores that actually do remain and are not re-circulated. Finding an experimental value lower than the theoretical one is consistent with reality. We therefore used the experimental value of F (0.57) for the spore balance calculation.

Whole-greenhouse Botrytis spore balance

Figures 6 (a and b) show examples of the daily (24-hours) time series of the main terms of the spore balance – exchange with the outside ($FG(C_e - C_i)$), spore deposition ($D_i \Delta t$), and spore production ($P_i \Delta t$) – for the April 2004 and May 2005 trials.

For the April 2004 trial, which lasted 29 days, the spore production was always positive or nil, except during 3 days when a small negative value was observed. As already said, a negative spore production makes no sense either biologically or physically and is probably due to errors or imprecision in the balance setup. It is the case for example, when the difference ($C_e - C_i$) is weak, as in April 2003 and when consequently the sign of this difference can change because of small imprecision's in the measurements of C_e or C_i .

As the rose crop gets older, as for the May 2005 trial (Figure 6 b), spore production increases substantially and becomes systematically positive (export of spores due to an internal production), as indicated by the negative value of the transfer term $FG(C_e - C_i) \Delta t$ during about half that period. For the same trials, Table 1 gives the average values of the different terms of the balance for measurement periods both before the rose crop was planted (April 2003) and after (April 2004 and May 2005) and Table 2 summarizes the statistical values for the different terms of the balance corresponding to measurements performed after the rose crop was planted (October 2003, April 2004, November 2004 and May 2005).

The spore concentration difference between inside and outside ($C_e - C_i$) can vary widely from one period to another with, for example, an inside concentration three times lower than outside during the April 2004 trial (0.8 sp m^{-3} vs 2.7 sp m^{-3}), whereas inside and outside concentrations are approximately the same during the April 2003 and May 2005 trials. Statistical analysis of the components of the *Botrytis cinerea* spore balance on a daily basis for the four trials performed after the rose crop was planted (Table 2) together with the time trend in spore concentrations (Fig. 7) show that, on average, the inside spore's concentration remains fairly stable (0.8 sp m^{-3} , with a standard deviation= 0.05 sp m^{-3}) throughout the trials, whereas the outside concentration varies widely (from 0.8 sp m^{-3} to 3 sp m^{-3} , with a standard deviation= 1 sp m^{-3}). On a daily basis, spore production ($P_i \Delta t$) is equal to 11,176 sp before

rose crop planting in April 2003 (Table 1) and reaches an average of 83,939 sp for the trials performed after planting (Table 2). Overall, increasing inside spore production is observed as the crop ages (Table 1).

Table 1 also shows that total spore deposition D_i (sp s⁻¹) (impaction plus sedimentation) can vary widely, from 0.65 sp s⁻¹ in April 2003, before the rose crop was planted, to 2.9 sp s⁻¹ in May 2005. The caption of Table 2 indicates that impaction represents only 20% of the total spore deposit, the major deposition being on horizontal surfaces (80% of the total deposition). With these new figures in mind, one can discuss one of the major assumptions of this study which is recall in section 2: “all spores deposited on the surfaces of soil or leaves remain there and do not return to the air”. One can then distinguish between the deposition on soil, ultimate horizontal surface, for which this assumption is true and the vertical deposition on leaves, buds and stems, which concerns only 20% of the total spore’s deposition, and for which this assumption can still be discussed.

Total spore deposition depends not only on inside spore concentration C_i but also on the inside air speed and leaf area index values for the part corresponding to impaction on the crop canopy. Figure 8 presents the measured time trends for spore deposition (impaction plus sedimentation) and for the whole-greenhouse air exchange rate. For the various trials, one can observe the similarity between the courses of spore deposition and greenhouse ventilation intensity. As shown by Wang *et al.* (1999) greenhouse ventilation is also proportional to inside air speed, consequently, on average we also have a fairly close correlation between inside spore deposition and inside air speed. A similar trend was already observed on a daily time scale for only sedimentation (Fig. 5) and is also confirmed for a period lasting between 3 and 4 weeks for sedimentation and impaction together.

On average, taking into account all four trials performed after the rose crop was planted (October 2003, April 2004, November 2004 and May 2005), two thirds of the spores deposited inside were also produced inside, one-third coming from outside. However, very wide variations can occur from one period to another, as between the April 2004 and May 2005 trials (Fig. 9), with a general tendency for an increasing inside production as the crop grows old.

4-3- Comparison of spore balance results with observations of sporulation

The crucial task of independently verifying spore production is hard to perform because quantitative sampling is almost impossible in a rose crop. Because of its saprophytic capacity *Botrytis c.* produces spores on small crop debris (detached petals, leaves, stems),

1 which are difficult to detect, and petal spotting, which appears post-harvest on rose flowers.
2 Consequently, there are few symptoms of infection that can be detected in the greenhouse.

3 Based on systematic observations performed weekly, the first *Botrytis c.* sporulation
4 was observed in July 2004 on plant debris but we cannot be sure that there was no
5 fructification before that time, as it is very difficult to detect spore production on crop debris
6 in a production scale greenhouse. Similarly, the first symptoms of petal flecking on rose
7 flowers in the greenhoouse were observed some time later, during the November 2004 trial.
8 These roses were sampled and the samples (33) were placed in humid chambers; 100% of
9 them gave fructifications.

10 Figure 10 summarizes the results of spore production (P) calculated from equation (4) with
11 the qualitative observations of spore production. It shows the increase in inside sporulation,
12 whereas the term of spore exchange with the outside can vary widely from one period to
13 another. When the level of inside sporulation is high the spore exchange term can even be
14 negative, indicating spore exportation, as in May 2005. More generally, there is an observable
15 coherence between the general tendency for increasing inside spore production as the crop
16 ages, as revealed by the spore balance, and the observation of *Botrytis c.* sporulation and petal
17 spotting which occur respectively three and seven months after the first detection of a
18 substantial increase in inside spore production.

19 20 5 - Conclusion

21 Although some uncertainty still attaches to our results as applied on a daily basis, this first
22 attempt to perform a *Botrytis cinerea* spore balance inside a rose greenhouse gives plausible
23 results if we take the average values for the different terms of the balance for an entire
24 measurement period, i.e. between 15 and 30 days, and compare these quantitative results with
25 more qualitative results on *Botrytis c.* sporulation. On this time scale, the main value of the
26 method is that it enables us to determine the origin and evolution of the inocula, and in
27 particular to state whether they came from inside or outside the greenhouse. It also enables us
28 to identify and analyse, even sometimes on a time scale shorter than several weeks, the factors
29 influencing spore concentration inside the greenhouse, such as ventilation rate, outside
30 concentration, spore production and spore deposition on the rose crop canopy, with other
31 factors such as inside spore concentration, crop surface area and air speed. The study also
32 stresses the possibility of analysing the evolution of *Botrytis cinerea* establishment in a
33 perennial crop such as roses.

However, this method is based on one major assumption, i.e. that “all the *Botrytis cinerea* spores that grow on the Keressies medium and are counted can also potentially grow on the rose crop and contribute to the rose crop’s *Botrytis* balance”. Of course this assumption requires further validation by complementary studies assessing the biodiversity of *Botrytis cinerea* strains (Chave *et al.*, 2004). It will then be possible to exploit this approach for studying more systematically the determination by biotic and non-biotic factors of *Botrytis cinerea* spore production within the greenhouse, and to confirm our first assessment that the spores in the greenhouse come predominantly from the outside, at least when the rose crop is young. It would then be possible to analyse the consequences of these findings for fungal development and the crop’s agronomic performance.

Acknowledgements: This study was partly supported by the 2004-2006 Franco-Korean specific agreement on the “Development of an aerodynamic model to study microclimate of tomato canopy and predict pathogenic spore transfer” conducted by INRA (France) and NIAE-RDA (Republic of Korea). Thanks are also addressed to the trainee’s engineer or teacher Ms Fanny Girardot and Christine Nieto who have actively participated to the project.

Tables:

Variables	April 2003 trial Mean value	April 2004 trial Mean value	May 2005 trial Mean value
$G \text{ (m}^3 \text{ s}^{-1}\text{)}$	4.1	1.7	7.9
$C_e \text{ (sp m}^{-3}\text{)}$	0.8	2.7	0.8
$C_i \text{ (sp m}^{-3}\text{)}$	0.6	0.8	0.9
$D_i \text{ (sp s}^{-1}\text{)}$	0.6	1.9	2.9
$FG(C_e - C_i)\Delta t \text{ (sp)}$	30,017	104,197	-14,615
$D_i\Delta t \text{ (sp)}$	43,418	160,231	249,713
$P_i\Delta t \text{ (sp)}$	11,176	54,891	266,329

Table 1: Components of the *Botrytis cinerea* spore balance on an average daily basis for the April 2003 (10 days), April 2004 (30 days) and May 2005 (14 days) trials.

Variables	Average of the 4 trials			
	Mean value	Minimum	Maximum	Standard deviation
$G \text{ (m}^3 \text{ s}^{-1}\text{)}$	2.4	0.4	7.9	3.1
$C_e \text{ (sp m}^{-3}\text{)}$	1.8	0.8	3.0	1.0
$C_i \text{ (sp m}^{-3}\text{)}$	0.85	0.8	0.9	0.05
$D_i \text{ (sp s}^{-1}\text{)}$	1.4	0.4	2.9	0.95
$FG(C_e - C_i)\Delta t \text{ (sp)}$	35,853	-14,615	22,359	45,000
$D_i\Delta t \text{ (sp)}$	122,083	37,857	249,713	80,876
$P_i\Delta t \text{ (sp)}$	85,939	14,308	266,329	96,776

Table 2: Components of the *Botrytis cinerea* spore balance on an average daily basis for the four trials performed after the rose crop was planted (October 2003, April 2004, November 2004 and May 2005). On average the deposition on vertical surfaces due to impaction represents only 20% of the total horizontal (D_h) plus vertical (D_v) deposit.

Figures

Figure 1: Method for identifying the origin of *Botrytis cinerea* inocula using a spore balance

Figure 2: Transverse cross section of the 576 m² experimental greenhouse.

Figure 3: Plan of the greenhouse with positioning of the biological and climate measurements.

- Horizontal spore deposition traps using 90 mm ø Petri dishes with a Kerssies medium, placed at a height of 2.5 m.
 - Horizontal spore deposition traps using 90 mm ø Petri dishes with a Kerssies medium, placed just above soil level.
 - △ Vertical spore impactation traps using 90 mm ø Petri dishes with a Kerssies medium, placed at a height of 2.5 m.)
 - ⬡ Suction volumetric spore traps (Burkard)
 - Central greenhouse climate sensors (T, RH) using the greenhouse's climate computer devices (L'ien, Vitrolles, France)
- Wind speed and direction were measured outside the greenhouse at 5.5 m high about 15 meters apart West of the greenhouse.
