Abstract

Metmyoglobin (MbFe^{III}), a major form of dietary iron, is an efficient inducer of lipid and protein oxidation. Indeed, MbFe^{III} is able to cleave hydrogen peroxide and lipid hydroperoxides with subsequent formation of ferrylmyoglobin ($\text{MbFe}^{\text{IV}}=\text{O}$) and lipid oxyl and peroxy radicals. In the first part of this work, the mechanism of the reaction between MbFe^{III} and H_2O_2 is revisited with an emphasis on the influence of bovine serum albumin (BSA). BSA does not affect the rate of $\text{MbFe}^{\text{IV}}=\text{O}$ formation but inhibits the formation of the redox-inactive green pigment (heme-protein cross-link species). Although tightly bound to BSA, the flavonol quercetin is still able to reduce $\text{MbFe}^{\text{IV}}=\text{O}$ as a likely result of long-range electron transfers within a protein-protein complex. In a second part, BSA is shown to strongly slow down the metmyoglobin-catalyzed consumption of linoleic acid hydroperoxides with formation of ketones as the main products. In the process, only low concentrations of ferrylmyoglobin are slowly accumulated. A catalytic mechanism is proposed that involves a one-electron oxidized metmyoglobin species distinct from ferrylmyoglobin.

Keywords: Metmyoglobin; Hydrogen peroxide; Lipid hydroperoxide; Quercetin; Serum albumin; Free radicals.

Introduction

The reaction of myoglobin (MbFe^{II}) and metmyoglobin (MbFe^{III}) with hydrogen peroxide has been thoroughly studied for its implication in the oxidative deterioration of meat [1] and, more generally, its relevance in the development of oxidative stress via lipid and protein modifications [2-4]. Since myoglobin and metmyoglobin are the main forms of dietary iron, these heme proteins could also trigger lipid peroxidation in the gastric compartment following a meal including red meat (the main source of heme iron) and polyunsaturated lipids [5]. In such circumstances, traces of lipid hydroperoxides could replace H_2O_2 for the activation of heme iron to hypervalent forms involved in the initiation of the peroxidation process [6]. Protection against this diet-related oxidative stress could have nutritional significance from at least two viewpoints: the preservation of dietary lipids essential to cell functioning and the protection against the toxicity of potentially harmful lipid oxidation products (hydroperoxides, aldehydes, epoxides) and the highly reactive radical intermediates (*e.g.*, lipid oxyl and peroxy radicals) involved in their formation [7]. Interestingly, given their low ability to cross the intestinal barrier (absorption), common dietary plant antioxidants such as polyphenols could have their antioxidant action essentially restricted to the gastro-intestinal (GI) tract [8]. However, the peroxidase activity of MbFe^{III} is clearly dependent on several factors such as pH, the hydroperoxides under consideration and the presence of other proteins, which could interact with MbFe^{III} and/or the antioxidant [2]. As part of our ongoing program to investigate the heme-induced peroxidation of polyunsaturated dietary lipids and its inhibition by antioxidants [9,10], we now wish to report on the influence of bovine serum albumin (BSA) and the flavonol quercetin, one of the most common flavonoid aglycones in plants and in human diet, on the peroxidase activity of metmyoglobin. This study provides a basis for the rationalization of the heme-induced peroxidation of protein-stabilized lipid emulsions in food and in the GI tract [11]. It can also be noted that serum albumin is the carrier of the fraction of dietary polyphenols that enters the blood circulation (as conjugates) following intestinal absorption [12,13].

Materials and methods

Chemicals

Horse heart myoglobin (MbFe^{II}, MW *ca.* 17600 g mol⁻¹), hydrogen peroxide (30% in water), quercetin and bovine serum albumin (fraction V A-9647, MW *ca.* 66500 g mol⁻¹) were purchased from Sigma-Aldrich. Upon dissolution in the phosphate buffer, MbFe^{II} is quickly converted into MbFe^{III} by autoxidation. The phosphate buffer (5 mM, pH 5.8) was prepared with Millipore Q-Plus water and passed through a column of Chelex-100 chelating resin (Bio-Rad) to remove contaminating metal ion traces. The preparation and purification of the linoleic acid hydroperoxides were carried out as described in the literature [14]. Based on the contamination of the samples by the corresponding (redox inactive) alcohols and ketones, a purity of *ca.* 80% can be assumed.

Absorption and emission spectra

Absorption spectra were recorded on a Hewlett-Packard 8453 diode-array spectrometer equipped with a quartz cell (optical pathlength: 1 cm). The temperature in the cell was kept at 37°C by means of a water-thermostated bath. Magnetic stirring in the cell at a constant rate (1000 rpm) was ensured by a Variomag stirrer (Telemodul 20C). Steady-state fluorescence spectra were recorded at 37°C on a thermostated Safas Xenius spectrofluorometer. The excitation and emission slit widths were set at 10 nm.

Formation of ferrylmyoglobin and its reduction by quercetin

A 60 μM solution of metmyoglobin (MbFe^{III}, concentration determined spectrophotometrically using $\epsilon = 7700 \text{ M}^{-1} \text{ cm}^{-1}$ at 525 nm) in the pH 5.8 phosphate buffer was thermostated at 37°C in the spectrophotometer cell in the presence or absence of BSA (3 equiv.). After a few minutes, 30 μL of a concentrated aqueous solution of H₂O₂ (4 mM, concentration determined spectrophotometrically using $\epsilon = 39.4 \text{ M}^{-1} \text{ cm}^{-1}$ at 240 nm) were added (final H₂O₂ concentration in the cell = 60 μM). The conversion of MbFe^{III} into ferrylmyoglobin (MbFe^{IV}=O) and its subsequent auto-reduction was monitored by the increase

of the absorbance at 590 nm over a few minutes. The procedure was repeated with H₂O₂ in excess (10 equiv.) for the determination of the molar absorption coefficient of MbFe^{IV}=O.

In the experiments with 1 equiv. H₂O₂, 20 µL of a concentrated solution of quercetin in MeOH (final quercetin concentrations in the cell: 15, 30 and 60 µM) were added once the formation of MbFe^{IV}=O was completed. Then, the reduction of MbFe^{IV}=O was monitored at 590 nm (time interval between 2 consecutive spectra = 0.5 s).

In the absence of quercetin, the set of equations used in the curve fitting procedures is as follows (A₀: initial absorbance, C: total heme iron concentration):

$$A(590 \text{ nm}) = A_0[\text{MbFe}]/C + \epsilon_1[\text{MbFe=O}] + \epsilon_2[\text{oxMbFe}] + \epsilon_3[\text{GMbFe}] \quad (1)$$

$$-\frac{d}{dt}[\text{MbFe}] = -\frac{d}{dt}[\text{H}_2\text{O}_2] = (k_1 + k_3)[\text{MbFe}][\text{H}_2\text{O}_2] \quad (2)$$

$$\frac{d}{dt}[\text{MbFe=O}] = k_1[\text{MbFe}][\text{H}_2\text{O}_2] - k_2[\text{MbFe=O}] \quad (3)$$

$$\frac{d}{dt}[\text{oxMbFe}] = k_2[\text{MbFe=O}] \quad (4)$$

$$\frac{d}{dt}[\text{GMbFe}] = k_3[\text{MbFe}][\text{H}_2\text{O}_2] \quad (5)$$

In the presence of BSA, the formation of GMbFe was neglected ($k_3 = 0$, $\epsilon_3 = 0$).

In the presence of quercetin (Q), one simply has:

$$-\frac{d}{dt}[\text{MbFe=O}] = k_r[\text{MbFe=O}][\text{Q}] - k_2[\text{MbFe=O}] \quad (6)$$

$$-\frac{d}{dt}[\text{Q}] = k_r[\text{MbFe=O}][\text{Q}] \quad (7)$$

Activation of MbFe^{III} by the linoleic acid hydroperoxides

Kinetic analysis by UV-vis spectroscopy in the visible range. In a first series of experiments, 30 µL of a 10.8 mM solution of LOOH in 2-propanol (*i*-PrOH) were added to 2 mL of a MbFe^{III} and BSA solution (respective concentrations = 60 and 180 µM) in the pH 5.8 phosphate buffer at 37°C. In a second series of experiments, to facilitate the solubilization of LOOH, an equimolar solution of BSA and LOOH (150 µM, *i*-PrOH content < 1.5%) was prepared, stirred for a few minutes and transferred to the spectrometer cell (2 mL). Then, 0.1 mL of a 1.25 mM MbFe^{III} solution in the phosphate buffer was added. Final concentrations in the cell were 180 µM for BSA, 144 µM for LOOH and 60 µM for MbFe^{III}. After A(590 nm)

had reached a constant value, 20 μL of a concentrated solution of quercetin in MeOH were added (final quercetin concentrations = 30-125 μM). The same procedure was repeated with 8 equiv. LOOH. Experiments without BSA were also carried out by using a minimal LOOH concentration (0.8 equiv.).

In the experiments with BSA and 9- or 13-LOOH in excess (8 equiv.), the slow development of ferryl absorption in the visible range was analyzed according to the following kinetic model:

$$A(590 \text{ nm}) = A_0[\text{MbFe}]/C + \epsilon_1[\text{MbFe=O}] + \epsilon_a[\text{MbFe} - 1e^-] \quad (8)$$

$$-\frac{d}{dt}[\text{MbFe}] = (k_1 + k_a)[\text{MbFe}][\text{LOOH}] - k_b[\text{MbFe} - 1e^-][\text{LOOH}] \quad (9)$$

$$\frac{d}{dt}[\text{MbFe} - 1e^-] = k_a[\text{MbFe}][\text{LOOH}] - k_b[\text{MbFe} - 1e^-][\text{LOOH}] \quad (10)$$

$$\frac{d}{dt}[\text{MbFe=O}] = k_1[\text{MbFe}][\text{LOOH}] \quad (11)$$

$$-\frac{d}{dt}[\text{LOOH}] = (k_1 + k_a)[\text{MbFe}][\text{LOOH}] + k_b[\text{MbFe} - 1e^-][\text{LOOH}] \quad (12)$$

$$\frac{d}{dt}[\text{L=O}] = (k_1 + k_a)[\text{MbFe}][\text{LOOH}] \quad (13)$$

Kinetic analysis by spectroscopic monitoring of the Soret band: The same procedure was applied with the following final concentrations: 0 or 9 μM for BSA, 9.6 μM for LOOH (added last) and 3 μM for MbFe^{III}. The experiment was repeated with H₂O₂ (3 μM) for comparison.

Kinetic analysis of LOOH consumption by HPLC: The same procedure was applied with the following final concentrations: 0 or 18 μM for BSA, 24 μM for LOOH, 6 μM for MbFe^{III} (added last). Every 30 s, a volume of 0.2 mL was taken up and acidified with 10 μL of 0.12 M HCl. After addition of 0.2 mL of tetrahydrofurane/CH₃CN (2:3), the mixture was centrifuged for 3 min at 10⁴ rpm and the upper layer frozen until HPLC analysis according to already described conditions [14].

Quenching of the fluorescence of the quercetin-BSA by metmyoglobin

The fluorescence intensity of the quercetin-BSA complex (noted I_F) at 535 nm is gradually quenched by increasing concentrations of the metmyoglobin ligand (noted L). The

experimental procedure is as follows: to 2 mL of an equimolar solution of BSA and quercetin (concentration = 40 μM) in the pH 5.8 phosphate buffer placed in the spectrofluorometer cell were added small samples (10 μL) of a 450 μM metmyoglobin solution in the same buffer. Assuming a 1:1 binding between the two proteins, an optimized value for the binding constant (K) was estimated by fitting the I_F vs. L_t curve against Eqs. (14)-(16) where L_t is the total MbFe^{III} concentration, C the total BSA concentration and f_P the molar fluorescence intensity of the quercetin-BSA complex (the fluorescence of free quercetin is negligible).

$$I_F = f_P[P]\exp[-(\varepsilon_L^{ex} + \varepsilon_L^{em})lL_t] \quad (14)$$

$$L_t = [L](1 + K[P]) \quad (15)$$

$$C = [P](1 + K[L]) \quad (16)$$

Since MbFe^{III} substantially absorbs light at the excitation and emission wavelengths (450 and 535 nm, respectively), an inner filter correction is necessary. In Eq. 1, the ε_L parameters stand for the molar absorption coefficients of MbFe^{III} at the excitation and emission wavelengths. Their values are determined independently by UV-visible spectroscopy from a Beer's plot ($\varepsilon_L = 8300$ and $6500 \text{ M}^{-1} \text{ cm}^{-1}$ at 450 and 535 nm, respectively). Finally, l is the mean distance travelled by the excitation light at the site of emission light detection. For the spectrometer used in this work, l is estimated to be 0.65 cm.

Data analysis

The curve-fitting and derivation procedures of the absorbance vs. time plots were carried out on a PC using the *Scientist* program (MicroMath, Salt Lake City, USA). Beer's law and sets of differential kinetic equations with initial conditions on concentrations were given as input data. Curve-fittings were achieved through least square regression and yielded optimized values for the parameters (kinetic rate constants, molar absorption coefficients).

Results and discussion

All experiments have been conducted in mildly acidic conditions (pH 5.8) corresponding to the pH of meat and of the gastric compartment experiencing the buffering effect of the dietary bolus in the early phase of digestion [15].

Activation of metmyoglobin by hydrogen peroxide

The complete set of the reactions taking place between metmyoglobin and H_2O_2 is presented on Scheme 1. Hydrogen peroxide triggers a two-electron oxidation on MbFe^{III} with the simultaneous formation of an iron-oxo center ($\text{Fe}^{\text{IV}}=\text{O}$) and a protein radical located on Tyr-103 or Trp-14. This activated form of metmyoglobin is called perferrylmyoglobin ($\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$). In the absence of external sources of electrons, perferrylmyoglobin rapidly evolves toward the more stable ferrylmyoglobin ($\text{MbFe}^{\text{IV}}=\text{O}$) upon a poorly understood process called auto-reduction. During auto-reduction, Mb is the most likely source of electrons and actually dityrosine residues can be evidenced along the globin chain [16]. Alternatively, in slightly acidic solutions, a second pathway can occur that probably originates from a protonated form of $\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$ ($\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}-\text{OH}$) and consists in the formation of a covalent bond between the porphyrin nucleus and Tyr-103. In this process, a green pigment ($\text{GMbFe}^{\text{III}}$) is formed [17,18]. In the presence of external sources of electrons (antioxidants, polyunsaturated lipids, proteins), both $\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$ and $\text{MbFe}^{\text{IV}}=\text{O}$ can be reduced. In particular, $\text{MbFe}^{\text{IV}}=\text{O}$ is a potent initiator of lipid peroxidation [6,19] while $\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$ efficiently abstract electrons from proteins to produce long-lived protein radicals [16,20]. In its more oxidizing protonated form ($\text{pK}_a \approx 5$), ferrylmyoglobin is as efficient as $\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$ at producing protein radicals from BSA as judged from the amount of diTyr produced [20]. Finally, $\text{MbFe}^{\text{IV}}=\text{O}$ itself can evolve by a slow auto-reduction process. Its reduction by various antioxidants including several polyphenols has been investigated [9,21-23].

When a mildly acidic solution of MbFe^{III} (visible absorption maximum at 505 nm + minor band with a maximum at 635 nm) is treated by H_2O_2 , the formation of $\text{MbFe}^{\text{IV}}=\text{O}$ can be evidenced by the increase in visible absorption at 550 and 590 nm (Fig. 1A). When the experiments are repeated in the presence of BSA (3 equiv.), significant changes can be

observed: although BSA does not alter the visible spectrum of MbFe^{III}, its influence on the activation process is manifested by the band at 550 nm being now slightly more intense than the band at 590 nm while the reverse is obvious in the absence of BSA (Fig. 1B). In fact, the final spectrum is very similar to the one of MbFe^{IV}=O at neutral pH [21-23] *i.e.* in conditions where the formation of the green pigment is negligible. Thus, we propose that BSA essentially quenches the formation of GMbFe^{III}, which in the absence of BSA is manifested by the development of a strong absorption at 590 nm in agreement with the literature [6].

Because MbFe^{IV}=O is contaminated by the inert GMbFe^{III} in the absence of BSA, the subsequent step of MbFe^{IV}=O auto-reduction or reduction by quercetin is manifested by relatively small spectral changes since the potential for regeneration of MbFe^{III} from MbFe^{IV}=O is low (Fig. 2). By contrast, BSA ensures a large conversion of MbFe^{III} into MbFe^{IV}=O and a subsequent large regeneration of MbFe^{III} either by auto-reduction or, much more rapidly, by electron transfer from quercetin (Fig. 2). Since BSA radicals are known to be produced from the reaction of BSA with Mb•Fe^{IV}=O [16,20,24], the transient intermediate in MbFe^{III} activation, part of quercetin can also be consumed by electron transfer to the BSA radicals themselves. In addition, the slow decay of MbFe^{IV}=O in the presence of BSA, which is slightly faster than in the absence of BSA, could reflect not only the auto-reduction process but also the reduction of the iron-oxo center by BSA.

For a quantitative kinetic analysis, a simplified set of reactions between metmyoglobin and H₂O₂ was considered (Scheme 2). The calculations (see Experimental Section for details) were first run in the simpler situation of MbFe^{III} reacting with H₂O₂ in the presence of BSA (GMbFe^{III} neglected). After H₂O₂ addition (1 equiv.), the A(590)-time curve was recorded over 30 min (Fig. 2A) for the monitoring of MbFe^{IV}=O formation (fast step, second-order rate constant k_1) and subsequent decay (slow step, first-order rate constant k_2) into an oxidized Fe^{III} species noted oxMbFe^{III}. When the reaction is repeated with an excess of H₂O₂ (10 equiv.), the decay of MbFe^{IV}=O is no longer detectable (Fig. 2B) and the plateau value of A(590 nm) can now be used to estimate the molar absorption coefficient of MbFe^{IV}=O: $\epsilon_1 = 9450 (\pm 110) \text{ M}^{-1} \text{ cm}^{-1}$ ($n = 2$). On the other hand, the curve-fitting of the A(590 nm) vs. time curves collected with 1 equiv. of H₂O₂ allows to estimate k_2 as well as the molar absorption coefficient of oxMbFe^{III}: $k_2 = 18.8 (\pm 0.7) \times 10^{-4} \text{ s}^{-1}$, $\epsilon_2 = 4820 (\pm 40) \text{ M}^{-1} \text{ cm}^{-1}$ ($n = 2$). Then, sets of experiments on shorter periods of time (2-3 min) were run (1 equiv. of H₂O₂) to estimate k_1 (k_2 and ϵ_2 set constant at their values previously determined): $k_1 = 640 (\pm 110) \text{ M}^{-1} \text{ s}^{-1}$ ($n = 6$). At the end of each run, quercetin (MbFe^{III}/quercetin molar ratio = 1, 2 and 4) was

added to monitor the kinetics of its oxidation by $\text{MbFe}^{\text{IV}}=\text{O}$ (Fig. 2C). From the concentrations of the different heme species determined prior to quercetin addition and taking into account $\text{MbFe}^{\text{IV}}=\text{O}$ auto-reduction (k_2 value previously determined), the decay of A(590 nm) could be analyzed to extract the second-order rate constant k_r for the reduction of $\text{MbFe}^{\text{IV}}=\text{O}$ by quercetin: $k_r = 680 (\pm 120) \text{ M}^{-1} \text{ s}^{-1}$ ($n = 6$).

To address the more complicated situation of MbFe^{III} activation and subsequent reduction in the absence of BSA, the rate constant k_1 for the formation of $\text{MbFe}^{\text{IV}}=\text{O}$ and its molar absorption coefficient ϵ_1 were set at mean values estimated in the presence of BSA. Then, the A(590)-time curves recorded over 30 min with 1 equiv. of H_2O_2 (Fig. 2A) were analyzed according to a kinetic model assuming the competitive formation of $\text{MbFe}^{\text{IV}}=\text{O}$ and $\text{GMbFe}^{\text{III}}$ (rate constant k_3 , molar absorption coefficient ϵ_3) from MbFe^{III} and the subsequent auto-reduction of $\text{MbFe}^{\text{IV}}=\text{O}$ into $\text{oxMbFe}^{\text{III}}$. We thus obtained estimates for the auto-reduction rate constant of $\text{MbFe}^{\text{IV}}=\text{O}$ in the absence of BSA and the molar absorption coefficients of $\text{oxMbFe}^{\text{III}}$ and $\text{GMbFe}^{\text{III}}$: $k_2 = 30.1 (\pm 1.8) \times 10^{-4} \text{ s}^{-1}$, $\epsilon_2 = 4580 (\pm 200) \text{ M}^{-1} \text{ cm}^{-1}$ (in good agreement with the value in the presence of BSA), $\epsilon_3 = 12230 (\pm 1150) \text{ M}^{-1} \text{ cm}^{-1}$ ($n = 2$). As previously (in the presence of BSA), sets of experiments on shorter periods of time (2-3 min) were finally run (1 equiv. of H_2O_2) to obtain a refined value for k_3 (k_1 , k_2 , ϵ_1 , ϵ_2 and ϵ_3 set constant at their values previously determined), the $\text{MbFe}^{\text{IV}}=\text{O}$ concentration at the time of quercetin addition and the value of the rate constant k_r of its oxidation by $\text{MbFe}^{\text{IV}}=\text{O}$: $k_3 = 270 (\pm 110) \text{ M}^{-1} \text{ s}^{-1}$ ($n = 6$), $k_r = 73 (\pm 15) \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$ ($n = 4$).

Remarkably, BSA-bound quercetin remains able to reduce $\text{MbFe}^{\text{IV}}=\text{O}$ although the corresponding rate constant is one order of magnitude smaller than in the absence of BSA. This is consistent with the propagation of radicals from $\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$ to BSA [16,20,24] and with our recent work that suggests the possibility of efficient long-range electron transfers connecting the periphery of serum albumin (which provides primary sites for oxidative attacks) and the quercetin binding site in sub-domain IIA [25]. It is also noteworthy that some reductants such as ascorbate and Trolox are able to reduce ferrylmyoglobin by two distinct mechanisms: a weak binding to the heme pocket with a subsequent fast reduction of the ferryl center and a stronger binding to another site followed by a relatively slow long-range electron transfer involving a critical Tyr residue [26].

The main results of the kinetic analysis are summarized in Table 1. In the literature [27], the rate constant for the formation of $\text{MbFe}^{\text{IV}}=\text{O}$ has been shown to be independent of

pH in the range 5 – 7. From the apparent first-order rate constant reported ($35 \times 10^{-4} \text{ s}^{-1}$ for initial MbFe^{III} and H_2O_2 concentrations of $10 \text{ }\mu\text{M}$), a k_1 value of $350 \text{ M}^{-1} \text{ s}^{-1}$ can be calculated at 25°C , which is consistent with our value of $640 \text{ M}^{-1} \text{ s}^{-1}$ at 37°C . Unlike k_1 , the rate constant of ferryl auto-reduction (k_2) is strongly dependent on pH in the range 5-7 and sharply increases when the pH is lowered as a result of the formation of a protonated ferryl species. From the same article [27], the value estimated at pH 5.8 and 25°C is *ca.* $5 \times 10^{-4} \text{ s}^{-1}$, which is 6 times lower than the value estimated in our work. From the mean values of the rate constants, the concentrations of the different heme species following the addition of hydrogen peroxide to a mildly acidic solution of metmyoglobin can be plotted as a function of time in the presence or absence of serum albumin (Fig. 3). In the absence of BSA, it can be seen that the percentage of heme-protein cross-linked species ($\text{GMbFe}^{\text{III}}$) amounts to slightly less than 30% of the total heme concentration at pH 5.8 and 37°C . A previous work using reverse-phase HPLC for the titration of the different heme species in solution concluded that this percentage is about 15% at room temperature [17].

In addition, an investigation by fluorescence spectroscopy suggests that metmyoglobin is able to bind to the quercetin-BSA complex ($K \approx 10^5 \text{ M}^{-1}$ based on our work [13]). Indeed, whereas we were unable to gain evidence of a direct interaction between metmyoglobin and quercetin (no significant quenching of the MbFe^{III} intrinsic fluorescence pertaining to its Trp residues), a strong quenching of the fluorescence of the quercetin-BSA complex (excitation of bound quercetin at 450 nm, emission collected at 535 nm) was observed by increasing metmyoglobin concentrations (Fig. 4). A mathematical treatment of the quenching curve (see Experimental Section) provided the corresponding binding constant: $K = 24.7 (\pm 1.1) \times 10^3 \text{ M}^{-1}$ (pH 5.8, 37°C) ($n = 2$). Hence, we propose that the reduction of ferrylmyoglobin by BSA-bound quercetin takes place within a complex in which both proteins are associated.

In summary, BSA does not alter the activation of metmyoglobin into ferrylmyoglobin upon oxidation by H_2O_2 (nor the rate of ferrylmyoglobin auto-reduction) but quenches the covalent coupling between the heme cofactor of protonated $\text{Mb}^{\bullet}\text{Fe}^{\text{IV}}=\text{O}$ and the globin chain, possibly by direct reduction of the protein radical. In addition, BSA-bound quercetin is still able to reduce $\text{MbFe}^{\text{IV}}=\text{O}$ (although less rapidly than in the absence of BSA). Consistently, quercetin efficiently inhibits lipid peroxidation in BSA-stabilized emulsions [11].

Activation of metmyoglobin by linoleic acid hydroperoxides

Even in the absence of hydrogen peroxide, MbFe^{III} is a potent initiator of lipid peroxidation [2,6,9,10]. By analogy with investigations dealing with organic hydroperoxides, this process likely reflects the ability of metmyoglobin to cleave traces of lipid hydroperoxides (LOOH) with concomitant formation of highly oxidizing species such as MbFe^{IV}=O and LO• (homolytic cleavage) and/or Mb^{•+}Fe^{IV}=O (heterolytic cleavage with simultaneous formation of LOH) [28]. However, during the metmyoglobin-induced peroxidation of linoleic acid, no significant formation of MbFe^{IV}=O can be evidenced. On the other hand, a concomitant decay of the Soret absorption band is observed that suggests a degradation of the porphyrin nucleus [9,10]. Hence, the true initiating species is not precisely characterized. A partially oxidized form of MbFe^{IV}=O can be assumed.

In this work, the reaction is investigated in details by using purified linoleic acid hydroperoxides (LOOH, mixture of 9-(10*E*,12*Z*)-LOOH, 9-(10*E*,12*E*)-LOOH, 13-(9*Z*,11*E*)-LOOH and 13-(9*E*,11*E*)-LOOH) contaminated by minor amounts of the corresponding alcohols (LOH) and ketones (L=O) [14]. The HPLC analysis of LOOH consumption confirms that the reaction is fast in the absence of BSA and follows an apparent first-order kinetics with $k_{\text{obs}} = 155 (\pm 6) \times 10^{-3} \text{ s}^{-1}$ (Fig. 5). The ketones come up as the major products of hydroperoxide consumption (apparent first-order rate constant for L=O formation = $105 (\pm 19) \times 10^{-3} \text{ s}^{-1}$) whereas the concentration of the corresponding alcohols (LOH) remains low and quasi-constant (data not shown). Thus, during the reaction, the L=O/LOH molar ratio increases from 0.7 to 3.3. The amount of lipid oxidation products distinct from L=O and LOH (*e.g.*, epoxyalcohols, cleavage products) is *ca.* 30%. By contrast, 13-(9*Z*,11*E*)-LOH makes a major contribution to the products formed in the reaction of metmyoglobin with 13-(9*Z*,11*E*)-LOOH at pH 7.4 and 25°C [29]. The bimolecular rate constant k for the reaction between LOOH and MbFe^{III} can be roughly evaluated from $k_{\text{obs}} = kC_0$ (C_0 : initial metmyoglobin concentration = 6.2 μM). One obtains: $k \approx 25 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$. Given the obvious lack of sensitivity due to fast LOOH consumption (Fig. 5), this value can be regarded as a lower limit of the true k value. In the literature [27], the pseudo-first order rate constant for LOOH consumption following addition of MbFe^{III} was estimated from the decay of the absorbance at 234 nm, which is characteristic of conjugated dienes. From the k_{obs} value at pH 6 (*ca.* 0.1 s^{-1} , initial MbFe^{III} concentration = 10 μM), one obtains: $k = 10^4 \text{ M}^{-1} \text{ s}^{-1}$ at 25°C, which is consistent with our estimation at 37°C. It is also noteworthy that a sharp increase in k_{obs} was

observed when the pH was lowered from 6.5 to 5 [27]. This acceleration was ascribed to the formation of a protonated ferryl species with a radical character permitting its reaction with a second LOOH equivalent to form a lipid peroxy radical LOO[•].

Although much slower, the consumption of BSA-bound LOOH gives similar results (Fig. 5): the ketones are the main products (final L=O/LOH molar ratio = 4.1, 20% of other lipid oxidation products). The apparent rate constants for LOOH consumption and L=O formation are $11.5 (\pm 3.0) \times 10^{-3} \text{ s}^{-1}$ et $8.8 (\pm 1.8) \times 10^{-3} \text{ s}^{-1}$, respectively. Hence, we deduce: $k \approx 18 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$. The fact that the consumption of linoleic acid hydroperoxides by metmyoglobin is strongly slowed down by BSA probably reflects LOOH-BSA binding. Similarly, the accommodation of linoleic acid molecules to the typical fatty acid binding sites of human serum albumin efficiently protects linoleic acid against the peroxidation induced by hydrophilic peroxy radicals generated in the aqueous phase [25].

Importantly, metmyoglobin promotes the complete consumption of the hydroperoxides in large excess (4 equiv.) in less than 1 min in the absence of BSA and in *ca.* 10 min in the presence of BSA (0.74 equiv.). Simultaneously, at least 2 equivalents of ketones are produced. Hence, it is clear that a recycling of MbFe^{III} takes place so that sub-stoichiometric MbFe^{III} concentrations are sufficient. The fact that ketones are the major products is consistent with a homolytic LOOH cleavage leading to MbFe^{IV}=O and lipid oxyl radicals (LO[•]). Indeed, the major fate of the LO[•] radicals (besides possible epoxidation and/or cleavage into aldehydes and C-centered radicals) is ketone formation through a fast sequence of 1,2-shift of H-atom with subsequent addition of O₂ on the C-centered radical thus formed and elimination of the hydroperoxyl radical (HOO[•]) (Scheme 3) [30]. Moreover, a process quickly regenerating MbFe^{III} from MbFe^{IV}=O must operate. In the absence of BSA, LOOH themselves are the most likely reducing agents for this task in agreement with previous investigations [27,29]. In the reduction of MbFe^{IV}=O by LOOH, LOO[•] radicals are produced (Scheme 3). A similar mechanism was proposed for the formation of epoxyalcohols in the reaction of metmyoglobin with 13-(9Z,11E)-LOOH at pH 7.4 and 25°C [29]. It is consistent with the observation that one O₂ molecule is consumed for the consumption of every two hydroperoxide molecules.

Monitoring the reaction between MbFe^{III} and LOOH in the visible range shows a slow development of a weak absorption at 590 nm typical of ferrylmyoglobin (Fig. 6). In the presence of BSA, this process is of apparent first-order and largely independent of the hydroperoxide regioisomers selected and of the order of addition of the reagents (MbFe^{III} and

LOOH). With LOOH in large excess (8 equiv.), the accumulation of MbFe^{IV}=O is followed by a slow decay (data not shown) whose apparent first-order rate constant ($14 (\pm 7) \times 10^{-4} \text{ s}^{-1}$, $n = 2$) is consistent with the auto-reduction rate constant already estimated. The plateau concentration of MbFe^{IV}=O (deduced from the molar absorption coefficient previously obtained) is in the range 5 - 30% of the initial MbFe^{III} concentration depending on the initial LOOH concentration (1 - 8 equiv.). This low concentration suggests that MbFe^{IV}=O is involved in reactions with LOOH [29] and possibly BSA [20] which prevent its substantial accumulation. It is also noteworthy that even at pH 7.4 and 25°C, *i.e.* in conditions where MbFe^{IV}=O is expected to be much more stable, its contribution to the total heme concentration is no higher than 40% after a 15 min incubation of MbFe^{III} and 13-(9Z,11E)-LOOH (5 equiv.) [29].

The apparent first-order rate constant for ferryl accumulation depends on the initial LOOH concentration: $k_{\text{obs}} = 29 (\pm 10) \times 10^{-4} \text{ s}^{-1}$ (2.4 equiv. LOOH, $n = 4$), $299 (\pm 98) \times 10^{-4} \text{ s}^{-1}$ (8 equiv. LOOH, $n = 7$). In the absence of BSA, k_{obs} can also be estimated from the weak biexponential increase of A(590 nm) observed after addition of 9-LOOH or 13-LOOH in low concentration (0.8 equiv.) to ensure complete solubility: $k_{\text{obs}} = 412 (\pm 30) \times 10^{-4} \text{ s}^{-1}$ ($n = 2$). The order of magnitude of the bimolecular rate constant for the reaction between MbFe^{III} and LOOH can be deduced from $k_{\text{obs}} = k_1 C_0$ (C_0 : initial LOOH concentration): $k_1 = 20 - 60$ and $900 \text{ M}^{-1} \text{ s}^{-1}$ in the presence and absence of BSA, respectively. Although crude, those estimates are clearly much smaller than the values deduced from the conversion of LOOH into L=O (2×10^3 and $25 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ in the presence and absence of BSA, respectively). Similar discrepancies between the rate constants of LOOH consumption and ferryl formation were already pointed out in the investigation of the reaction between MbFe^{III} and 13-(9Z,11E)-LOOH in neutral conditions [29]. They were interpreted by assuming that only a fraction of the MbFe^{III} population is reactive owing to a conformational change in the protein chain caused by oxidative damage and making the heme pocket more accessible to the LOOH molecule. However, a preliminary oxidative damage required to prime MbFe^{III} for reacting with LOOH should create lag phases in LOOH consumption and ferryl formation. They were not observed (Figs. 5 and 6).

A plausible mechanism for the metmyoglobin-induced decomposition of linoleic acid hydroperoxides has to account for the following observations: a catalytic MbFe^{III} concentration is sufficient; low ferryl concentrations are slowly accumulated; LOOH consumption is at least one order of magnitude faster than ferryl accumulation; when two

LOOH molecules are consumed, approximately one L=O molecule is formed. The following mechanism can be proposed (Scheme 3): in a first step, MbFe^{III} rapidly reacts with LOOH (rate constant k_a) to form L=O, a one-electron oxidizing species (possibly, a hydroperoxyl radical) that is dissipated through the protein moiety and a new heme species equivalent to a one-electron oxidized metmyoglobin (molar absorption coefficient ε_a). This species oxidizes a second LOOH molecule into the LOO[•] radical (leading to other lipid oxidation products) with regeneration of metmyoglobin (rate constant k_b). In parallel, minor concentrations of MbFe^{IV}=O accumulates (rate constant k_1 , molar absorption coefficient ε_1) via homolytic LOOH cleavage. Using this kinetic model, ferryl formation following the addition of LOOH (8 equiv.) to the metmyoglobin solution (Fig. 6B) can be successfully analyzed ($r \geq 0.999$) by using the ε_1 value of $9450 \text{ M}^{-1} \text{ cm}^{-1}$ determined previously (Table 1) and by identifying the second-order rate constant for LOOH consumption estimated by HPLC ($k = 18 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$) with $k_a + k_1$. Thus, one obtains: $k_b = 373 (\pm 151) \text{ M}^{-1} \text{ s}^{-1}$ ($n = 6$), $\varepsilon_a = 2410 (\pm 190) \text{ M}^{-1} \text{ cm}^{-1}$ ($n = 6$). As for the rate constant of ferryl formation, it was found slightly higher with 13-LOOH than with 9-LOOH: $k_1 = 146 (\pm 11)$ (13-LOOH, $n = 3$) and $100 (\pm 7)$ (9-LOOH, $n = 3$) $\text{M}^{-1} \text{ cm}^{-1}$. From the values of the rate constants, the concentrations of the different species following the addition of linoleic acid hydroperoxides to a mildly acidic solution of metmyoglobin can be plotted as a function of time in the presence of serum albumin (Fig. 7). Alternative mechanisms involving MbFe^{IV}=O in the catalytic cycle or assuming a simple MbFe^{III}-catalyzed dehydration of LOOH into L=O failed to account for the whole set of experimental observations. The main results of the kinetic analysis are summarized in Table 2.

Adding quercetin after MbFe^{IV}=O has reached its plateau concentration brings about a fast decrease of A(590 nm), which can be analyzed by assuming a second-order reaction between MbFe^{IV}=O and quercetin (Fig. 6B). The corresponding rate constant ($k_r = 2660 (\pm 500) \text{ M}^{-1} \text{ s}^{-1}$, $n = 4$) is higher than the one obtained when H₂O₂ is used for the formation of MbFe^{IV}=O, as a possible consequence of the conformational changes in the BSA structure caused by the binding of LOOH and/or their products.

After addition of LOOH, the decay of the Soret band ($\lambda_{\text{max}} = 410 \text{ nm}$) of MbFe^{III} (Fig. 8) is of apparent first-order in the presence of BSA ($k_{\text{obs}} = 12 (\pm 2) \times 10^{-4} \text{ s}^{-1}$, $n = 2$) and biexponential in its absence with a fast step characterized by $k_{\text{obs}} = 294 (\pm 63) \times 10^{-4} \text{ s}^{-1}$ ($n = 2$). Moreover, the decay of A(410 nm) is much weaker than after addition of H₂O₂. In the latter case, the decay of A(410 nm) is independent of BSA, of apparent first-order ($k_{\text{obs}} = 44.6$

(± 2.3) $\times 10^{-4} \text{ s}^{-1}$, $n = 4$) and paralleled with the increase in A(430 nm), which is characteristic of MbFe^{IV}=O and is not observed with LOOH. Thus, the weak decay of the Soret band of metmyoglobin after addition of the linoleic acid hydroperoxides suggests relatively minor changes at the heme and is consistent with the marginal formation of ferrylmyoglobin.

The rate constant for the reaction between MbFe^{III} and H₂O₂ that can be estimated from k_{obs} ($k_1 = 1500 \text{ M}^{-1} \text{ s}^{-1}$) is higher (a factor 2) than the one estimated by monitoring the formation of MbFe^{IV}=O at 590 nm. This discrepancy could reflect the fact that the perferrylmyoglobin intermediate (Mb•Fe^{IV}=O) is not exclusively converted into MbFe^{IV}=O.

In summary, the kinetic analysis of the reaction between MbFe^{III} and LOOH shows that the fast accumulation of linoleic acid-derived ketones cannot be ascribed to the sole homolytic cleavage of the linoleic acid hydroperoxides with subsequent formation of ferrylmyoglobin. In fact, the slow and marginal accumulation of MbFe^{IV}=O (evidenced by the kinetic analyses at 590 and 410 nm), even in the presence of LOOH in large excess, suggests the occurrence of an alternative pathway independent of MbFe^{IV}=O and involving a much more reactive one-electron oxidized form of metmyoglobin (Scheme 3). This heme species is also the likely initiator of lipid peroxidation in mildly acidic solutions of linoleic acid [9,10].

Although BSA strongly slows down LOOH consumption and the decay of the Soret band as a likely consequence of LOOH-BSA binding and possible ROS scavenging by BSA, the overall mechanism appears unchanged and also leads to ketone accumulation. Interestingly, the ferrylmyoglobin thus formed can be quickly reduced by BSA-bound quercetin, which confirms the possibility of long-range electron transfers taking place along the BSA structure from quercetin (bound to sub-domain IIA) to the iron-oxo center of ferrylmyoglobin, itself bound to BSA [25].

Conclusion

BSA can bind metmyoglobin and modulates its reactivity with hydroperoxides. Presumably because of their own binding to BSA, linoleic acid hydroperoxides are much more slowly converted into the corresponding ketones in the presence of BSA. In the presence or absence of BSA, the formation of ferrylmyoglobin is marginal in agreement with a dominant process involving a distinct one-electron oxidized form of metmyoglobin, which absorbs only weakly in the visible range. With hydrogen peroxide, a more contrasted situation emerges. On the one hand, the literature shows that BSA can reduce the hypervalent iron

species (perferrylmyoglobin, protonated ferrylmyoglobin) it forms by reacting with metmyoglobin as evidenced by the detection of long-lived BSA radicals. On the other hand, our work also shows that BSA does not affect the rate of ferrylmyoglobin formation while inhibiting the competitive formation of the redox-inactive green pigment in mildly acidic conditions. Finally, by binding quercetin BSA lowers but does not abolish its ability to reduce ferrylmyoglobin due to possible long-range electron transfers taking place within the ferrylmyoglobin – BSA – quercetin ternary complex.

Table 1

Kinetic analysis of metmyoglobin reactions with hydrogen peroxide in the presence or absence of BSA (see Scheme 2 for kinetic model and text for details)

Rate constant	Mean value
k_1 (MbFe ^{IV} =O formation) ^a	640 M ⁻¹ s ⁻¹
k_2 (MbFe ^{IV} =O auto-reduction) ^a	30x10 ⁻⁴ s ⁻¹ (no BSA) 19x10 ⁻⁴ s ⁻¹ (+ BSA)
k_3 (GMbFe ^{III} formation, no BSA) ^a	270 M ⁻¹ s ⁻¹
k_r (MbFe ^{IV} =O + quercetin) ^b	73x10 ² M ⁻¹ s ⁻¹ (no BSA) 680 M ⁻¹ s ⁻¹ (+ BSA)

^a Curve-fitting of the spectral changes at 590 nm following the addition of H₂O₂ (60 or 600 equiv.) to a MbFe^{III} solution (60 μM) in the presence or absence of BSA (180 μM).

^b Curve-fitting of the spectral changes at 590 nm following the addition of quercetin (15, 30 or 60 μM) to MbFe^{III} (60 μM) previously activated by H₂O₂ (60 μM) in the presence of BSA (180 μM). The MbFe^{IV}=O concentration at the time of quercetin addition was deduced from the kinetic analysis of the activation step (see text).

Table 2

Kinetic analysis of metmyoglobin reactions with linoleic acid hydroperoxides in the presence or absence of BSA (see text for details)

Rate constant	Mean value
LOOH consumption ^a	$\geq 25 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$ (no BSA) $18 \times 10^2 \text{ M}^{-1} \text{ s}^{-1}$ (+ BSA)
MbFe ^{IV} =O formation ^b	$900 \text{ M}^{-1} \text{ s}^{-1}$ (no BSA) $100 - 150 \text{ M}^{-1} \text{ s}^{-1}$ (+ BSA)
k_r (MbFe ^{IV} =O + quercetin) ^c	$2700 \text{ M}^{-1} \text{ s}^{-1}$ (+ BSA)

^a Curve-fitting of the LOOH vs. time curves obtained by HPLC monitoring. Initial concentrations are 6.2 μM for MbFe^{III}, 25.5 μM for LOOH and 0 or 18 μM for BSA.

^b Curve-fitting of the spectral changes at 590 nm following the addition of LOOH (48 μM in the absence of BSA, 144 or 464 μM in the presence of 180 μM BSA) to a MbFe^{III} solution (60 μM). Experiments with addition of MbFe^{III} to a solution of LOOH and BSA were also carried out in the same conditions.

^c Curve-fitting of the spectral changes at 590 nm following the addition of quercetin (30 or 60 μM) to MbFe^{III} (60 μM) previously activated by LOOH (464 μM) in the presence of BSA (180 μM). MbFe^{IV}=O concentration at the time of quercetin addition estimated from $\epsilon(\text{MbFe}^{\text{IV}}=\text{O}, 590 \text{ nm}) = 9500 \text{ M}^{-1} \text{ cm}^{-1}$.
