Keywords: Simulation, Discrete Event Systems, DEVS formalism, Observation, Methodology

Abstract: The observation of a simulation is an important task of the modeling and simulation activity. However, this task is rarely explained in the underlying formalism or simulator. Observation consists to capture the state of the model during the simulation. Observation helps understand the behavior of the studied model and allows improving, analyzing or debugging it. In this paper, we focus on appending an observation mechanism in the Parallel Discrete Event System Specification (PDEVS) formalism with guarantee of the reproducible simulation with or without observation mechanism. This extension to PDEVS allows us to observe models at the end of the simulation or according to a time step. Thus, we define a formal specification of this extension and its abstract simulators algorithms. Finally, we present an implementation in the DEVS framework VLE.

1 INTRODUCTION

In the Modeling and Simulation (M&S) activity, observation of the behavior of models is an important aspect. An observation captures the state or the evolution of the state during or at the end of the simulation. It allows the modeler to test, prove, validate, or generate data from simulations by connecting simulation software application to output streams like files, databases, unit test or visualization software. Observations contribute to the modelers representation of its studied system.

In environmental and agronomic modeling domain, we need to couple heterogeneous models. These models can be continuous or discrete. In addition, these models co-exist in different temporal and spatial scales. Thus, to solve this problem, we use the Discrete Event Specification System (DEVS) formalism (Zeigler et al., 2000). DEVS can be seen as a common denominator for multi-formalism hybrid systems modeling (Vangheluwe, 2000). DEVS takes place in the M&S theory defined by B. P. Zeigler. M&S theory tends to be as general as possible. It addresses major issues of computer sciences from artificial intelligence to model design and distributed simulations. M&S theory aims to develop a common framework, formal and operational, for the specification of dynamical systems.

Modeling the observation process is dependent on the underlying formalism. However, for many formalisms, the observation does not exist and the outputs of models are used directly. For example, the numerical integration method Euler used for solving ordinary differential equations does not allow catching variable between two time-steps. The observation process is generally not explicit nor specified in the formalism. Specify the observation process is generally not useful. However, it becomes necessary when we want to observe multi-models with the same observation mechanism.

However, the DEVS formalism does not propose observation of simulation models. Several solutions exist without changing the behavior of DEVS. For example, in the first picture of the figure 1, outputs of the models A and B are connected to an observation model O. O has a reactive behavior. PowerDEVS (Bergero and Kofman, 2010) chooses this solution. It is simple and has great flexibility. However, it can be very expensive. Indeed, in the case of experimental frames (to calibrate or estimate parameters or to optimize parameters on criteria), only the final values of the observations are necessary. All the values received are useless. The interpretation of these values can be costly. In the second picture of the figure 1, an observation model O generates events to observed models A and B. These models send their outputs to the observation model. This solution is computationally less expensive, but requires mixing observation and normal behavior of the model. This mechanism can induce a difficulty in reproduc-
ing simulations and can increase the complexity of model.

We chose in this work to modify the DEVS formalism by adding an extension. This addition does not change the behavior of DEVS. It adds a layer of observation to DEVS. The DEVS trajectories of the simulations are the same with or without this extension. However, some alternatives exist to add an observation mechanism. Thus, rather than developing the observation process in the formalism, researchers developed this process in the software part of their simulators. It is the choice made by JAMES 2 (Himmelspach and Uhrmacher, 2009) and OSA (Ribault et al., 2010). JAMES 2 uses the design pattern observation; OSA uses AOP (Aspect-oriented programming). The design pattern observation links for each model a list of observation component. This list has a function called notify. The model calls this function when it wants to send observation value. The observation component has a reactive behavior. This type of behavior can increase the calculation to perform the treatment of observation values from multi-models (e.g. Models that use formalism with different time advance function). Of course, through a combination of the visitor and observer design patterns, we can make active the behavior of the observation component.

In this paper, we propose to extend the PDEVS formalism with an observation mechanism. This extension to DEVS provides a generic way to observe heterogeneous models and it guarantees the same simulations when this mechanism is activated and when it is not.

This paper is divided into three parts. In the first part, we explain the PDEVS formalism. This formalism is the context of our work. Then, we develop our contribution in two parts. (1) We develop the formal specification of the observation extension. This specification guarantees to conserve the behavior of PDEVS. (2) We present the abstract simulators of the observation extension. Developers of PDEVS simulators software can use these abstract simulators to introduce the extension observation in their simulators. The last sections show an implementation of this extension in the software VLE and an example of use. Finally, we conclude this paper with conclusion and perspectives.

2 Method

DEVS (Zeigler et al., 2000) is a well-known and accepted formalism for the specification of complex discrete or continuous systems abstracted as a network of concurrent, timed and interacting models. DEVS provides a hierarchical and modular approach to modeling and simulation. The formalism supports two types of models: atomic and coupled models. Atomic models interact thought a well-defined set of input and output values enabling a software component based orientation to model representation. Atomic models can be combined to form coupled models, providing the constructs to the representation of complex models.

2.1 PDEVS formalism

PDEVS (Chow and Zeigler, 1994) extends the Classic DEVS essentially by allowing bags of inputs to the external transition function. Bags can collect inputs that are built at the same date, and process their effects in future bags. This formalism offers a solution to manage simultaneous events that could not be easily managed with Classic DEVS. For a detailed description, we encourage the reader to read the section 3.4.2 in chapter 3 and the section 11.4 in chapter 11 of Zeigler’s book (Zeigler et al., 2000).

PDEVS defines an atomic model as a set of input and output ports and a set of state transition functions:

\[ M = (X, Y, S, \delta_{int}, \delta_{ext}, \delta_{con}, \lambda, \tau) \]

With:

- \( X \) is the set of input values
- \( Y \) is the set of output values
- \( S \) is the set of sequential states
ta : S → R_0+ is the time advance function
δ_int : S → S is the internal transition function
δ_ext : Q × X^b → S is the external transition function
Q = {(s, e)|s ∈ S, 0 ≤ e ≤ ta(s)}
S is the set of total states,
e is the time elapsed since last transition
X^b is a set of bags over elements in X
δ_con : S × X^b → S is the confluent transition function, subject to δ_con(s, 0) = δ_int(s)
λ : S → Y is the output function

If no external event occurs, the system will stay in state s for ta(s) time. When e = ta(s), the system changes to the state δ_int. If an external event, of value x, occurs when the system is in the state (s, e), the system changes its state by calling δ_ext(s, e, x). If it occurs when e = ta(s), the system changes its state by calling δ_con(s, x). The default confluent function δ_con definition is:

δ_con(s, x) = δ_ext(δ_int(s), 0, x)

The modeler can prefer the opposite order:

δ_con(s, x) = δ_ext(δ_con(s, ta(s)), x)

Indeed, the modeler can define its own function. Every atomic model can be coupled with one or several other atomic models to build a coupled model. This operation can be repeated to form a hierarchy of coupled models. A coupled model is defined by:

N = (X, Y, D, {M_d}, {I_d}, {Z_i, d})

Where X and Y are input and output ports, D the set of models and:

∀d ∈ D, M_d is a PDEVS model
∀d ∈ D∪{N}, I_d is the influencer set of d :
I_d ⊆ D∪{N}, d /∈ I_d
∀d ∈ D∪{N},
∀i ∈ I_d, Z_{i, d} is a function,
the i-to-d output translation:
Z_{i, d} : X → X_d, if i = N
Z_{i, d} : Y → Y_d, if d = N
Z_{i, d} : Y → X_d, if i /≠ N and d /≠ N

The influencer set of d is the set of models that interact with d and Z_{i, d} specifies the types of relations between models i and d.

2.2 Extension Observation: Formal Specification

The development of simulation software based on DEVS formalism implies to observe models and their evolution during the simulation. Observation of DEVS models involves watching or capturing their states. These captures can be done when a change of state occurs (in DEVS terminology, in δ_int, δ_ext or δ_con transition functions) or at specific dates.

In DEVS, the solution generally used is to connect models, both inputs and outputs, to an observation model (see figure 2). This model has in charge to send observation messages and to process the responses of the models. For example, to build a discrete observation, the observation model relies on a constant ta function in order to send, at each time step, an event to observed models. Observed models compute observations and send them to the observer.

![Observation model](image)

This solution forces the modelers to merge the state graphs between observation and behavior of their models (See figure 3 for an explanation).

In addition, by merging the state graphs, the modeler might make the results of its models dependent to his observation. If model is observed asynchronously with its behavior, the computation of the elapsed time e when an external event disturbs an atomic model may introduce a floating-point error. Indeed, coordinator needs to call the external transition of the simulator with s, e, x parameters where e = t - tl with t the current time of the simulation (time of the perturbation) and tl the time of last event. If an internal state variable in S is based on e to compute its value in the δ_ext transition, its internal state variables can give different results with or without observations. Precisely,
this mismatch can be explained by the difficulty representing real number in computer engineering (Goldberg, 1991) (see the IEEE Standard for Floating-Point Arithmetic, IEEE 754).

If all models use integer as representation of the time (i.e. all time advance functions return duration in \( \mathbb{N} \)), the floating-point problem would not exist. However, in the domain of Environmental Modeling, the models use continuous and discrete event formalisms such as the QSS2 formalism (Kofman, 2002) which solves in \( \mathbb{R} \) a second order polynomial function in order to compute the duration in a state. They can hardly rely on a representation of the time in \( \mathbb{N} \).

The solution proposed does not change the value of \( e \) in the case of observation.

Finally, in DEVS, a model can have several states at the same date (when at least one call to the \( \tau \) function returns 0). These states are called transitory states. It seems obvious that the observation of the transitory states makes no sense. However, this solution does not guarantee to provide only observations of real model states. For example, if the observation is required at a specific time of simulation, the state observed can be one of these transitory states.

In this section, we propose a formal and operational representation of observations in the PDEVS formalism. This extension is based on a function of observation in atomic models and a second graph of connections in coupled models. This extension to the PDEVS formalism integrates necessary characteristics:

- First is to ensure that this extension does not disturb the simulation i.e. we need to conserve the same result with or without the observation.
- Second is to provide several types of observation. We propose, in this paper, two modes: time step and finish that define respectively: observations when a model reaches a time and observations at the end of the simulation (see figure 4).
- Third, the extension should not take its values directly from the state of the current model but from a function (see figure 4).
- Finally, in DEVS, state variables may change several times at the same date (when its \( \tau \) returns 0 or when an external event disturb it). In this case, we observe the last state of the model.

Thus, to develop this extension we need to add function to the atomic models, to add new set in coupled model and add specific observation models. We develop these changes in the next section.

### 2.2.1 PDEVS Atomic model

To develop this extension in the PDEVS formalism, we extend the PDEVS atomic model with new sets of input and output ports (\( X_{obs} \) and \( Y_{obs} \)). The first one is used for observation request; the second one is used for routing values returned by modeler. We attach to this port a new output function called \( \lambda_{obs} \). The new PDEVS atomic model is defined such as:

\[
M = (X, Y, S, X_{obs}, Y_{obs}, \delta_{in}, \delta_{ext}, \delta_{conf}, \lambda, \lambda_{obs}, \tau)
\]

Where:

\( X_{obs} \) are the ports used to catch observation requests.

\( Y_{obs} \) are the ports used to send observation values.

\[
\lambda_{obs} : X_{obs} \times S \times t_{obs} \rightarrow Y_{obs}
\]

\( s \in S \),

\( t_{obs} \) current time of the simulation.

Figure 3: This picture show state graphs of an atomic model. In left picture, we show the model without observation and in the right part, the same model with the capacity to be observed at any time (dotted lines represent external transitions). In the computation of the observation states \( Obs_{in}, \) \( Obs_A \) or \( Obs_B \) (in \( \delta_{ext}, \delta_{conf}, \delta_{in} \) or \( ta \) functions), simulators can introduce floating-point errors when computing the time elapsed since last transition (e in DEVS terminology) for example.
Figure 4: The first figure shows the evolution of the state $S$ of a system over time $t$. The second figure shows the model of this system in DEVS. This figure shows the trajectory of the state of the DEVS model. The last two figures show the observation value. Dots are observation values.

$\Delta_t$ unit time. $O_{\text{timed}}$ reads observation events from its port $X_{\text{obs}}$ and stores data transported by event. This model is:

$$ O_{\text{timed}} = \langle X_{\text{obs}}, Y_{\text{obs}}, S, X_{\text{obs}}, Y_{\text{obs}}, \delta_{\text{int}}, \delta_{\text{ext}}, \delta_{\text{con}}, \lambda, \lambda_{\text{obs}}, t_a \rangle $$

Where:

$X_{\text{obs}}$ is the set of observation values,
$Y_{\text{obs}}$ is the set of observation requests,
$S : \{\text{IDLE, SENT}\} \times Data$, with:

- IDLE, SENT: automata finite states,
- Data: output stream states.

$X_{\text{obs}} = \emptyset$
$Y_{\text{obs}} = \emptyset$

$\forall d \in Data : \delta_{\text{int}}((\text{IDLE}, d)) = (\text{SENT}, d)$
$\forall d \in Data : \delta_{\text{int}}((\text{SENT}, d)) = (\text{IDLE}, d)$
$\forall s \in \{\text{IDLE, SENT}\} :$

$$ \delta_{\text{ext}}(s, d, e, X_{\text{obs}}) = (s, d') $$

where $d'$ is the state of the output stream once $X_{\text{obs}}$ has been stored,

$\forall d \in Data : ta((\text{IDLE}, d)) = \Delta_t $ (the time step)
$\forall d \in Data : ta((\text{SENT}, d)) = 0$
$\forall s \in S : \lambda(s) = \text{observation}(s, t, x)$
$\lambda_{\text{obs}}$ is a null function

- The finish observer model, $O_{\text{finish}}$, produces observation events at the end of the simulation on its $Y_{\text{obs}}$ port and wait observation events from its port $X_{\text{obs}}$. $O_{\text{finish}}$ is the same model as $O_{\text{timed}}$ but, its $ta$ function returns the end of the simulation to build observation event, or $+\infty$ after.

$$ O_{\text{timed}} = \langle X_{\text{obs}}, Y_{\text{obs}}, S, X_{\text{obs}}, Y_{\text{obs}}, \delta_{\text{int}}, \delta_{\text{ext}}, \delta_{\text{con}}, \lambda, \lambda_{\text{obs}}, t_a \rangle $$

Where:

$X_{\text{obs}}$ is the set of observation values,
$Y_{\text{obs}}$ is the set of observation requests,
$S : \{\text{WAIT, END}\} \times Data$, with:

- WAIT, END: automata finite states,
- Data: output stream states.

$\forall d \in Data : \delta_{\text{int}}((\text{WAIT}, d)) = (\text{END}, d)$
$\forall d \in Data : \delta_{\text{int}}((\text{END}, d)) = (\text{END}, d)$
$\forall s \in \{\text{WAIT, END}\} :$

$$ \delta_{\text{ext}}((s, d), e, X_{\text{obs}}) = (s, d') $$

where $d'$ is the state of the output stream once $X_{\text{obs}}$ has been stored,

In this paper, we suggest two types of observers. $O_{\text{timed}}$ and $O_{\text{finish}}$ to respectively, send observation following a given time-step or at the end of the simulation.

- The discrete time observer model, $O_{\text{timed}}$, needs to send output events on its output port $Y_{\text{obs}}$ every

$\lambda_{\text{obs}}$ is a null function.

1\footnote{$X_{\text{obs}} = \emptyset, Y_{\text{obs}} = \emptyset$ and $\lambda_{\text{obs}}$ is a null function.}
\[
X_{\text{obs}}? = \emptyset \\
Y_{\text{obs}} = \emptyset \\
\forall d \in \text{Data} : ta((\text{WAIT},d)) = \text{end}
\]
where \text{end} is the duration of simulation\n\[
\forall d \in \text{Data} : ta((\text{END},d)) = +\infty
\]
\[
\forall s \in S : \lambda(s) = \text{observation}(s,t,x)
\]
\[
\lambda_{\text{obs}} \text{ is a null function}
\]

The function \text{observation} is a user defined function that identifies in \(Y_{\text{obs}}\) the observation request that should be sent to the observed models.

### 2.2.3 Coupled model

As seen earlier in the introduction and in the section 2.1, the \(I_d\) variable and the function \(Z_{r,d}\) define the graph of connections of the models by calculating the influenced models. Our observation extension of the PDEVS formalism uses the same principle. It proposes two subsets \(I_r\) and \(I_o\) that, respectively identify the influences of atomic models (responses of the observations) and the influences of observer models (models sending the request of observation).

We extend the PDEVS model coupled in order to introduce a second connection network (see the figure 5). This second network is dedicated to the observer models and to the classical PDEVS atomic models to observe through their ports \(X_{\text{obs}}?\) and \(Y_{\text{obs}}\). The new PDEVS coupled model is defined as:

\[
N = \{X, Y, D, O, R, X_{\text{obs}}?, X_{\text{obs}}, Y_{\text{obs}}, Y_{\text{obs}}?, X_{\text{obs}?}, Y_{\text{obs}?}, Y_{\text{obs}?}\} \\
\{M_d\}, \{I_d\}, \{Z_{r,d}\}, \{M_o\}, \{O_d\}, \{Z_{o,d}\}, \{M_r\}, \{R_d\}, \{Z_{r,d}\}
\]

Where \(X_{\text{obs}}?, Y_{\text{obs}}?\) and \(X_{\text{obs}?}, Y_{\text{obs}?}\) are input and output ports to route observation and request events. \(O\) is the set of names of observed models \(O \subseteq D, \{M_o\}\) is the set of observed models \(\{M_o\} \subseteq \{M_d\}\), \(R\) the set of names of observer models \(R \subseteq D\) and \(\{M_r\}\) is the set of observer models \(\{M_r\} \subseteq \{M_d\}\).

\[
\forall r \in R \cup \{N\}, \\
I_r \text{ is the influencer set of observed models of } r \\
L_r \subseteq O \cup \{N\}, r \notin I_r
\]

\[
\forall o \in O \cup \{N\}, \\
I_o \text{ is the influencer set of observed models of } o \\
L_o \subseteq R \cup \{N\}, o \notin I_o
\]

The observation network is however very constrained. Thus, the functions \(Z_{o,d}\) and \(Z_{r,d}\) are very different and provide additional constraints from the classical \(Z_{r,d}\) function. These additional constraints ensure that a DEVS atomic model cannot send an observation event to another DEVS atomic model, and an observation model cannot send request observation to another observation model. The figure 5 shows an example of connections between observed and observer models.

\[
\forall r \in R \cup \{N\}, \\
\forall d \in I_r, \exists \text{ an output translation function } Z_{r,d} : \\
Z_{r,d} : X_{\text{obs}}? \rightarrow X_{\text{obs}?}, \text{ if } r = N \\
Z_{r,d} : Y_{\text{obs}}, \rightarrow Y_{\text{obs}?}, \text{ if } d = N \\
Z_{r,d} : Y_{\text{obs}?}, \rightarrow X_{\text{obs}?}, \text{ if } r \neq N \text{ and } d \neq N
\]

\[
\forall o \in O \cup \{N\}, \\
\forall d \in I_o, \exists \text{ an output translation function } Z_{o,d} : \\
Z_{o,d} : X_{\text{obs}} \rightarrow X_{\text{obs}?}, \text{ if } o = N \\
Z_{o,d} : Y_{\text{obs}}, \rightarrow Y_{\text{obs}?}, \text{ if } d = N \\
Z_{o,d} : Y_{\text{obs}?}, \rightarrow X_{\text{obs}?}, \text{ if } o \neq N \text{ and } d \neq N
\]

**Figure 5:** In this picture, we illustrate the second network in the coupled model to deal with observations graph. Plain connections are observation requests from output port \(Y_{\text{obs}?}\) of observation models, to atomic model input port \(X_{\text{obs}?}\) or to coupled model’s output port \(Y_{\text{obs}?}\), or from coupled model input port \(X_{\text{obs}?}\) to atomic model \(X_{\text{obs}?}\). Dashed connections constitute response of observation request from extended PDEVS atomic model (on output port \(Y_{\text{obs}}\)) to observation model \(X_{\text{obs}}\) or coupled model output port \(Y_{\text{obs}}\). The atomic model \(B\) is observed by an external observation model on its port \(X_{\text{obs}2}\). It sends observations to its output port \(Y_{\text{obs}2}\). For this figure and for a better understanding, we distinguish observation ports for the model \(B\).

**Closure under coupling**

Since we keep unchanged the internal \(S\) of coupled or atomic models nor all sets of the PDEVS definition (\(\text{IMM}, \text{INF}(s), \text{CONF}(s), \text{EXT}(s)\) and \(\text{UN}(s)\) of
the coupled model), the PDEVS functions have the same content (See chapter 7 in (Zeigler et al., 2000) to complete formalization). The closure under coupling property of the extension observation for parallel DEVS is still verified.

2.3 Algorithms

2.3.1 Root coordinator

The root-coordinator implements the overall simulation loop. It sends messages to its direct subordinate (simulator or coordinator). The root-coordinator first sends an initialize message (init-message), and loop on internal transition (*-message) from its child to perform the simulation cycles until some termination conditions.

As describe in the listing 1, the root coordinator is unchanged in this extension.

2.3.2 Coordinator

In the coordinator algorithm, we add an additional variable \( t_b \), which indicates the last date of the simulation. This variable \( t_b \) detects the last PDEVS bags to ensure to observe the latest state of a model. We add a new bag, called mailobs to store all observation events to atomic models at a specific date. When \( t_b \) detect a change, the mailobs is flushed into the observation network using the functions \( Z_{ob, d} \) and \( Z_{o, d} \).

The coordinator’s algorithms are described in the listings 2. From l. 1 to l. 38: routes the message or stores in mailobs. From l. 40 to the end: to update the \( t_b \) variable and to send xobs? message to the atomic models.
2.3.3 Simulator

Lastly, this last section on the abstract simulators develops algorithm for the simulator of the atomic model. As presented previously, the management of the observations events is very simple for the modeler since only one function is called \( \lambda_{obs} \). This function is called only for classical atomic models when they receive an \( X_{obs?} \) event. When observation models receives \( X_{obs} \) event, they use the classical way when receiving input message (See \( x\text{-message} \) in PDEVS abstract simulators).

The listing 3 describes the simulators algorithms. In line 12: when receives an \( x\text{obs}\text{-message} \) from the parent, simulator computes the observation in the \( \lambda_{obs} \) function and sends the data (wrapped into an \( y\text{obs}\text{-message} \)) to the parent coordinator.

To validate this work, we made an implementation of this extension in the DEVS open source simulator VLE.

3 RESULT

These works have started with multi-disciplinary issues emerging from the interaction between computer scientists and biologists. Considering these works, we think that the integration of heterogeneous models and the respect of the M&S cycle are the key issues to provide a complete and reliable software environment for natural complex systems modeling. Therefore, VLE has evolved on a complete multi-modeling and simulation environment (Quesnel et al., 2009) and is now a generic environment for M&S, in Environmen-

tal Sciences, in Industry or Medicine. Many projects from two major French research institutes INRA and Cirad use VLE. For example, the RECORD project (Bergerz et al., 2012) is a large platform designed for developing and analyzing models of cropping systems.

3.1 VLE: Virtual Laboratory Environment

VLE is a set of programs and libraries software. These components are used to model, to simulate and to analyze multimodel. VLE offers a set of formalism developed with a DEVS BUS (Kim and Kim, 1996). The sub-formalisms are DESS, QSS 1 and QSS 2 numerical procedure for solving ordinary differential equations, Petri nets, finite state automaton (Moore, mealy, FDDEV and Harel statechart (Harel, 1987)), cellular automaton (Cell-DEVS and Cell-QSS) and agent decision making. These extensions are developed using a DEVS BUS i.e. these extensions are developed such as atomic model. Finally, VLE uses an open-source license and all the source code are available on its website including this observation extension.

Figure 6: DEVS BUS and multi-modeling. The events \((x, t), (y, t), (\ast, t), (\text{done}, tN)\) represent the bus.

3.2 Implementation

In our implementation of the PDEVS abstract simulator, we define an atomic model as a classical C++ class. Modeler must this class inherits this class to override the observation function and to benefit to the observation extension developed in the previous section.

The listing 4 shows a simplified representation (without constructor, destructor, and other members) of the class which permits to develop atomic model behavior:

- 1. 3-14: the classic PDEVS functions: \( tu, \delta_{int}, \delta_{ext}, \lambda \) and \( \delta_{ext} \).
3.3 Using models with VLE

The study of the models is very important in the modeling and simulation cycle. Generally, this analysis is performed with an experimental setting. Experimental frames as sensitivity analysis, replicas generation are used to study or to validate models. One important motivation in formalizing the observation process in PDEVS is to develop generic experimental frames, which ones rely on intensive observation of models.

VLE is an environment for M&S. It relies on a set of libraries for modeling, simulation and analysis. These libraries developed in C++ are available for several programming languages. Thus, in order to collaborate with users of statistical tools, we provide an interface to the program R (R Development Core Team, 2012). R is a tool and language for statistical computing. This package named RVLE allows the user to run simulations, changes its parameters and retrieves simulation results (from the extension observation). This package combined with another packages of R as the classical sensitivity package permit to build experimental frames to validate, explore and optimize models. On this principle, we also offer program and PYVLE JVLE to develop web services based on simulation.

4 CONCLUSION

In this paper, in section 2, we extend the PDEVS formalism to introduce the observation of models in the formalism. This work was motivated by the separation between the dynamics of the system and its observation as a fundamental issue. This addition to the formalism is closed under coupling and allows building observations in a hierarchical and modular manner. The abstract simulators necessary for this extension were provided. In addition, we provided an implementation of this observation extension in the VLE simulators. This DEVs extension is crucial for us to develop experimental design and to abstract observation from models dynamic. However, a type of observation is missing in these works. It concerns the event observation of atomic models. In PDEVS terminology, after each change in $\delta_{ext}$, $\delta_{con}$ or $\delta_{con}$ transition functions. We work on the formalization of this new type of observation.
