# MicroRNA-202 (*miR-202*) controls female fecundity by regulating medaka oogenesis

## Short title

Fish oogenesis and microARN-202

## Key words

Fish fertility, ovary, gonads, microRNAs, CRSIPR/Cas9, quantitative image analyses, microarray

## ABSTRACT

Female gamete production relies on coordinated molecular and cellular processes that occur in the ovary throughout oogenesis. In fish, as in other vertebrates, these processes have been extensively studied both in terms of endocrine/paracrine regulation and protein expression and activity. The role of small non-coding RNAs in the regulation of animal reproduction remains however largely unknown and poorly investigated, despite a growing interest for the importance of miRNAs in a wide variety of biological processes. Here, we analyzed the role of *miR-202*, a miRNA predominantly expressed in male and female gonads in several vertebrate species. We studied its expression in the medaka ovary and generated a mutant line (using CRISPR/Cas9 genome engineering) to determine its importance for reproductive success with special interest for egg production. Our results show that miR-202-5p is the biologically active form of the miRNA and that it is expressed in granulosa cells and in the unfertilized egg. The knock out (KO) of *miR-202* resulted in a strong phenotype both in terms of number and quality of eggs produced. Mutant females exhibited either no egg production or produced a drastically reduced number of eggs that could not be fertilized, ultimately leading to no reproductive success. We quantified the size distribution of the oocytes in the ovary of KO females and performed a genome-wide transcriptomic analysis approach to identify dysregulated molecular pathways. Together, cellular and molecular analyses indicate that lack of *miR-202* impairs the early steps of oogenesis/folliculogenesis and decreases the number of large (*i.e.* vitellogenic) follicles, ultimately leading to dramatically reduced female fecundity. This study sheds new light on the regulatory mechanisms that control the early steps of follicular development and provides the first

*in vivo* functional evidence that an ovarian-predominant microRNA may have a major role in female reproduction.

### Author summary

The role of small non-coding RNAs in the regulation of animal reproduction remains poorly investigated, despite a growing interest for the importance of miRNAs in a wide variety of biological processes. Here, we analyzed the role of *miR-202*, a miRNA predominantly expressed in gonads in vertebrate. We studied its expression in the medaka ovary and knocked out the *miR-202* genes to study its importance for reproductive success. We showed that the lack of *miR-202* results in the sterility of both females and males. In particular, it lead to a drastic reduction of both the number and the quality of eggs produced by females. Mutant females exhibited either no egg production or produced a drastically reduced number of eggs that could not be fertilized, ultimately leading to no reproductive success. Quantitative histological and molecular analyses indicated that *miR-202* KO impairs oocyte development and is also associated with the dysregulation of many genes that are critical for reproduction. This study sheds new light on the regulatory mechanisms that control oogenesis and provides the first *in vivo* functional evidence that an ovarian-predominant microRNA may have a major role in female reproduction.

# INTRODUCTION

In fish, female fecundity is tightly linked to the proper completion of oogenesis in the ovary, whereby undifferentiated germinal stem cells undergo meiosis, a dramatic increase in size and ultimately form the eggs (1). Such an important differentiation processes requires coordinated interactions between the oocyte and the surrounding somatic cells (granulosa and theca cells), which together form the ovarian follicles (2). While the role of endocrine and intra-ovarian factors in these processes has been extensively studied, the regulation by the small non-coding RNAs (microRNAs) has received far less attention (3)(4).

MicroRNAs (approximately 22 nucleotides in length) play many different biological functions through the post-transcriptional regulation of protein-coding genes. In mammals, most researches that investigate the role of miRNAs in the ovary have mainly relied on *in vitro* analyses. Numerous studies that have highlighted the role played by miRNAs in ovarian development and oogenesis, as shown for miR-224 (5)(6)(7). In contrast, data documenting the role played by miRNAs in fish reproduction remain scarce and mainly rely on expression studies. In zebrafish, the expression and regulation of specific miRNAs has been associated with vitellogenesis and follicular development (8). More specifically, expression and regulation of miR-17 and miR-430b in the ovary suggest a role in follicular development and oocyte maturation. Large scale differential transcriptomic analyses were also performed during sex differentiation, gonadal development or vitellogenesis in various fish species, including rainbow trout (9), zebrafish (10)(11), Atlantic halibut (12), yellow cat fish (13), Tilapia (14)(15) and medaka (16)(17). The identification of differentially expressed miRNAs through the different stages of the reproductive cycle is consistent with a participation of miRNAs in

oogenesis and spermatogenesis. Among the most abundantly expressed miRNA was *miR-202*, a miRNA known to be predominantly expressed in gonads in several vertebrate species, including frog (18), Atlantic halibut (19), human, mouse, rat (20)(21), chicken (22)(23), rainbow trout (24) and medaka (25). For protein-coding genes, such a predominant expression in gonads is usually associated with a major role in reproduction, as illustrated by many maternal-effect genes (26). There is however no functional evidence of the major role in fish reproduction of either *miR-202* or any other gonad-predominant miRNAs, although some recent *in vitro* studies reported a role for *miR-202* in mouse during spermatogenesis (27). Furthermore, it is currently unknown if such a critical feature, observed for protein-coding genes, would also be observed for miRNAs that are usually seen only as fine modulators of gene regulatory networks rather than major regulators of biological processes (28).

Here, we investigated the role of *miR-202* in fish reproduction with special attention for its role in the ovary. We thoroughly analyzed its cellular expression within the ovary and characterized the reproductive phenotype of *miR-202* knock-out (KO) fish, generated by CRISPR/Cas9 genome engineering. We showed that miR-202-5p is the predominant mature form expressed in granulosa cells. The lack of miR-202 resulted in a dramatic decrease of fertility in both male and females. In females, both egg number and quality were reduced, ultimately leading to the absence of any viable offspring. Quantitative image analysis of mutant ovaries showed that *miR-202* impairs the early steps of oogenesis/folliculogenesis. Along with this drastic phenotype, we observed the dysregulation of several key genes known for their role throughout oogenesis, as well as the dysregulation of genes, the role of which is not yet known in the ovary. Overall, this study sheds new light on the regulatory mechanisms that control the early steps of

follicular development and provides the first *in vivo* functional evidence that an ovarian-predominant microRNA has a major role in female reproduction.

## RESULTS

### MiR-202-5p is highly expressed in granulosa cells

The medaka miR-202 gene harbors two mature miRNAs sequences, miR-202-5p and miR-202-3p (Fig 1A), whose expression levels were surveyed by quantitative reverse transcription TaqMan PCR (TaqManPCR) in eleven different tissues of adult fish and during embryonic development. The miR-202-5p mature form was found specifically expressed at high levels in both gonads (*i.e.* ovary and testis), in comparison to all other tissues (Fig 1B). During embryonic development, the highest expression levels of miR-202-5p were detected in non-fertilized eggs at stage 0 (st.0), thus corresponding to a maternal accumulation (Fig 1C). Lower levels of miR-202-5p were detected from the one-cell stage (st.2) onward. A slight increased expression was detected just before hatching (st.39), likely corresponding to a zygotic transcription. The miR-202-3p mature form presented similar expression profiles in adult tissues but expression levels were approximately 1500 times lower in ovary and testis, in comparison to miR-202-5p and undetectable in other tissues. During development, miR-202-3p also exhibited a profile similar to the -5p form and could be detected in unfertilized eggs at levels 500 times lower, while it could not be detected above background levels at any other developmental stages (data not shown).

The cellular expression pattern of *miR-202* was analyzed in the ovary by fluorescent *in situ* hybridization (FISH) on ovarian sections (Fig 2). Ovaries were dissected either from juvenile females (*i.e.* before the first spawning) or from adult females (*i.e.* reproductively

active fishes). In both juvenile and adult ovaries, miR-202-5p was detected in follicles at all vitellogenic and post-vitellogenic stages, in granulosa cells surrounding the oocyte (Figs 2A' and 2B', arrowhead), but not in theca cells (Figs 2A' and 2B'', arrow). To visualize *sox9*-expressing cells in the germinal cradle, we performed FISH on ovaries from adult transgenic medaka *Tg(sox9b::EGFP)*. MiR-202-5p was detected in a subset of GFP-positive cells surrounding early pre-vitellogenic follicles (primordial follicles, Fig 2B'''). FISH performed with a specific MiR-202-3p probe (Fig 2C, D) or with a scramble control probe (S1 Fig) revealed no detectable signal above background.

### ***MiR-202* knock-out drastically reduces female fertility**

To determine the role of miR-202 on female reproduction, we inactivated the *miR-202* gene using the CRISPR/Cas9 technology. Small insertion/deletion (INDEL) mutations were inserted in the genome, in the miR-202-3p mature sequence (Fig 3A). Fishes displaying the same INDEL (-7+3) were selected to establish a mutant fish line. In homozygotes mutants (*miR-202*<sup>-/-</sup>), the processing of the pri-miR-202 was impaired and the miR-202-5p mature form was absent (Fig 3B). The sex ratio for both heterozygous and homozygous was the same as in wild-type siblings. This mutant line was used in all further experiments.

We thoroughly analyzed the reproductive phenotype of *miR-202*<sup>-/-</sup> adult females. The frequency of spawning was analyzed during ten consecutive cycles (Fig 3C). Two categories of mutant females were distinguishable by different reproductive phenotypes. The mildly affected females (subfertile females), which represented 85% of all mutant females analyzed, displayed an irregular frequency of spawning compared to wild-type females that spawned every day within one hour of the onset of the light. The

most strongly affected females (sterile females), which represented 15% of all mutant females analyzed, spawned only once in ten days. Further analysis of the quantity of spawned eggs (female fecundity) revealed that subfertile females spawned a significantly reduced number of eggs (5.8 eggs per clutch on average) compared to wild-type females (18.8 eggs per clutch on average, Fig 3D). In addition, the viability of embryos (*i.e.* capability of eggs to be fertilized and to develop correctly) was dramatically reduced when subfertile females were outcrossed with wild-type males (Fig 3E). Similar results were obtained when subfertile females were mated with mutant males. Conversely, when mutant males were outcrossed with wild-type females, the viability of embryos was also drastically affected compared to wild-type siblings. Further analysis of siblings revealed that, eggs originating from subfertile females fertilized by either a wild-type or a mutant male could not be fertilized, while eggs originating from wild-type females fertilized by a mutant male were fertilized but arrested during the first cleavage stages of embryonic development (st.4-5, Fig 3F). The overall reproductive success of mutant females was therefore reduced to 0.83 viable eggs per clutch for subfertile females (*i.e.* mutant females that exhibited irregular spawning, reduced fecundity and low embryonic survival) and to zero viable egg for sterile females that exhibited the most severe phenotype, while wild-type female exhibited an average of 15.3 viable eggs per clutch. To maintain the mutant fish line (INDEL -7+3), heterozygous fishes were thus systematically outcrossed with wild-type fishes at each generation (see Material and Methods). Another mutant line harboring another INDEL mutation (-8) was used to confirm this reproductive phenotype but this line was not used for further histological and molecular phenotyping analyses (data not shown).

Altogether, our results indicate that *miR-202* is required for the formation of functional gametes in both female and male gonads.

### ***MiR-202* knock-out affects the early steps of follicular growth in juvenile females**

We further analyzed the role of *miR-202* during oogenesis in juvenile females (*i.e.* before the first spawning). To this aim, the follicular content of wild-type and mutant ovaries were analyzed and compared. For each ovary, the number and size of follicles were determined on the median ovarian section. Nuclei of somatic cells, including granulosa cells surrounding each oocyte, were stained with DAPI, which allowed delineating all follicles and automatically individualizing them, using a computational automatic segmentation procedure (Fig 4A). The section area, the mean follicle diameter and the number of follicles were determined (Fig 4B). In *miR-202*<sup>-/-</sup> ovarian sections, the mean follicular diameter was significantly reduced (70  $\mu$ m), as compared to wild-type ovarian sections (80  $\mu$ m), and the number of follicles appeared higher (500  $\mu$ m) as compared to wild-type (300  $\mu$ m), although not significantly. These data suggest an impairment of the early follicular growth in juvenile mutant ovaries.

The size distribution of follicles on sections was thoroughly analyzed in mutant and wild-type ovaries. Follicles were classified according to their diameter into five different classes (<50  $\mu$ m, 50-100  $\mu$ m, 100-150  $\mu$ m, 150-200  $\mu$ m and 200-350  $\mu$ m) (Fig 4C). Comparison of the resulting profiles revealed different size distributions profiles in mutant and wild-type ovaries. In mutant ovarian sections, the number of small follicles appeared higher compared to wild-type, with a significant increased in the 50-100  $\mu$ m size class, whereas the number of follicles in the larger diameter class (200-350  $\mu$ m)

tended to decrease, although not significantly. This clearly suggests an important defect of the early follicular growth in juvenile *miR-202*<sup>-/-</sup> females, leading to an accumulation of small and medium oocytes (*i.e.* pre-vitellogenic and early-vitellogenic oocytes) to the detriment of larger late-vitellogenic and maturing follicles.

## ***MiR-202* knock-out decreases the number of growing follicles in subfertile adult females**

The role of *miR-202* during oogenesis was analyzed at the adult stage (reproductively active fish), in both subfertile and sterile females (Fig 5A). Section areas, mean follicular diameters and numbers of follicles were measured on median sections. The follicular size distribution was also analyzed. Follicles were classified according to their diameter into three different size classes based on their diameter: small (<100  $\mu\text{m}$ ), medium (100-400  $\mu\text{m}$ ) and large (400-1200  $\mu\text{m}$ ). In sterile females, ovaries displayed a significant decrease of the mean follicular diameter (170  $\mu\text{m}$ ) in comparison to wild-type ovaries (220  $\mu\text{m}$ ), but similar numbers of follicles were found in both cases. Consistently, ovarian sections were significantly reduced in mutant compared to wild-type (Fig 5B). The analysis of the size distributions also revealed distinct profiles in wild-types and mutants. The number of large follicles (>400  $\mu\text{m}$ ) was significantly reduced in mutant, while small follicles (<100  $\mu\text{m}$ ) tended to accumulate, although not significantly (Fig 5C). These observations suggest a strong impairment of the early steps of the follicular growth in sterile females, similarly to juvenile mutant females analyzed during the first reproductive cycle (see above).

In subfertile females, which exhibited a milder reproductive phenotype (*i.e.* occurrence of spawning but a reduced number of eggs and reduced egg survival), ovarian sections

displayed a significantly reduced number of follicles. This was associated with a significant reduction of ovarian section areas (Fig 5B). No modification of the mean follicular diameter was however observed, suggesting that although fewer follicles were engaged into growth, they were all able to reach their correct final size. This was supported by the follicular size distribution profiles, which showed a significant and important reduction of the number of medium-size follicles (100-400  $\mu\text{m}$  in diameter) in mutant compared to wild-type, and no accumulation of small-size follicles (<100  $\mu\text{m}$  in diameter, Fig 5C). These data likely reflect a milder effect of the *miR-202* deficiency on follicular growth in subfertile adult females compared to sterile fishes, indicating a partial recovery of the phenotype at this stage.

## Genome-wide analysis reveals major dysregulation of key ovarian genes

To get further insight into the molecular pathways that are affected in absence of *miR-202*, we performed a genome-wide transcriptomic analysis on ovaries of wild-type and *miR-202*<sup>-/-</sup> females. This analysis was conducted on ovaries from juvenile females, before the first spawning, when ovaries display a more homogenous follicle population (from 30 to 350  $\mu\text{m}$  in diameter) compared to ovaries from reproductively active adult fish (from 30 to 1100  $\mu\text{m}$  in diameter, see Figs 4 and 5). We identified 52 differentially expressed genes, including 11 genes that were up-regulated in mutant and 41 genes down-regulated in mutant (S1 Table). The most differentially expressed genes were validated by QPCR (*wnt2bb*, *wnt4a*, *klhl23*, *setd4*, *npr1b* and *srgap3*) along with other major genes involved in fish oogenesis selected from the literature (*cyp19a1a*, *cyp17*, *gsdf*, *inh*, *foxl2b*, *sycp3*, *foxl3*, *Sox9b*, *olvas*). Results are shown on figure 6 and are described below.

## Down-regulation of known genes expressed in the somatic germ-cell supporting cells (Fig 6A)

Expression analysis revealed a marked expression decrease of two genes encoding key steroidogenic enzymes (*cyp19a1a* and *cyp17*). *Cyp19a1a* (also known as aromatase) is an ovarian-specific steroidogenic enzyme that mediates estradiol (E2) production and therefore plays a major role in both sex differentiation and vitellogenesis (Lubzens et al. 2010, for review). An even more pronounced under-expression was observed for *cyp17* that acts upstream of *cyp19a1a*. Consistently, data obtained from microarray analysis also revealed the down-regulation of the *steroidogenic acute regulatory* gene (*star*, S1 Table). *Star* is involved in the cholesterol shuttling across the inner mitochondrial membrane, which is a rate-limiting step of the steroidogenesis (29)(30). A decrease in *star* expression indicates an overall decrease in ovarian steroidogenic production.

We also observed the down-regulation of *gsdf* and *inhibin*, two members of the TGF $\beta$  family, in the ovary of mutant females. *Gsdf* is known to be expressed in granulosa cells and to be involved in the maintenance and maturation of these cells (31)(32). *Inhibin* consists of a unique  $\alpha$  subunit and an activin  $\beta$  subunit. In the zebrafish ovary, members of the activin-inhibin-follistatin system exhibit dynamic changes in expression during folliculogenesis and the  $\alpha$  subunit (*inha*) is expressed during vitellogenesis, especially during final oocyte growth (*i.e.* prior to final oocyte maturation)(33).

Finally, QPCR analysis revealed a significant down-regulation of the transcription factor *foxl2b*, the only *foxl2* copy retained in medaka after teleost-specific genome duplication (34). In medaka, *foxl2b* is a female-specific gene expressed in somatic cells surrounding germ-cells in the germinal cradle. At later stages, *foxl2b* continue to be expressed in granulosa cells and in a minority of theca cells in pre-vitellogenic and vitellogenic

follicles, but expression ceased in post-vitellogenic follicles (35)(36). In mouse, *foxl2* is known as a key regulator of oogenesis and plays a critical role in ovarian differentiation (37)(38)(39).

#### **Down-regulation of known genes expressed in the primary oocyte within the germinal cradle (Fig 6B)**

We analyzed the expression of *sycp3*, *foxl3* (a *foxl2*-relative), *sox9b* and the medaka *vasa*-like gene (*olvas*). *Sycp3* and *foxl3* are both expressed in germ cells in the ovary and are both involved in the first meiotic division (4)(40). *Olvas* is known as a specific marker of early germ cells, which are nested in the cords of *sox9b*-expressing cells, referred to as the germinal cradle (41)(4). QPCR analysis revealed a down-regulation of *sycp3* and *foxl3* in the ovary of mutant females, although the diminution of *sycp3* expression is not significant. In contrast, the expression of *olvas* and *sox9b* was similar in wild-type and mutant ovaries. Together these observations suggest that germinal cradles of mutant ovaries are subjected to a reduced meiotic activity of primordial oogonia, while the mitotic activity of germline stem cells is likely to be maintained.

#### **Down-regulation of other genes that belong to the WNT and KELCH families (Fig 6C)**

Among the most differentially expressed genes were several other genes coding for proteins of the WNT signaling pathway, including *wnt2bb* and *wnt4a*. In ovary of mutant females, QPCR revealed a clear and significant down-regulation of *wnt2bb* and *wnt4a*. *Wnt4a* is expressed in fish ovary, while the expression of *wnt2bb* remains uncharacterized to date (42). The microarray analysis also revealed a dramatic down-regulation of *klhl23*, a member of the KELCH Like Family. KELCH proteins were initially characterized due to their important role in oocyte-somatic cells communication during

drosophila oogenesis. Several members of this large family (over 30 members) are known to be expressed in the ovary of several vertebrates even though they remain poorly studied (43).

#### Identification of novel molecular players of oogenesis (Fig 6D)

Finally, transcriptomic analysis revealed three other differentially expressed genes (*setd4*, *npr1b* and *srgap3*) that have never been previously described as molecular players of oogenesis. The *set domain-containing protein 4* (*setd4*) gene displayed a significantly reduced expression in ovary of mutant females. *Setd4* encodes for a recently characterized methyltransferase involved in breast cancer cell proliferation (44). While the role of *setd4* in the ovary remains unknown, a recent report demonstrated its role in the regulation of cell quiescence during the diapause of artemia embryos (45). The *natriuretic peptide receptor 1b* gene (*npr1b*) exhibited a marked over-expression. Although the role for *npr1b* in oogenesis has never been reported, the mouse *npr2* gene has already been detected in granulosa cells and shown to maintain meiotic arrest of oocytes in mouse ovary (46). The *slit-robo Rho GTPase activating protein 3* (*srgap3*) gene displayed a milder, yet significant, over-expression. Along with a well-established function in axon guidance, several studies suggested that the SLIT/ROBO pathway could also have important functions in the reproductive system (47). These results suggest that *setd4*, *npr1b* and *srgap3* are indeed novel molecular players of oogenesis. Given the greater number of down-regulated genes, in comparison to up-regulated genes, a non-annotated gene was selected for QPCR as a control and the profile observed on microarrays could be validated.

## DISCUSSION

Most of our current understanding of the regulatory mechanisms of oogenesis in fish is due to several decades of research on hormones, secreted factors or intrinsic signaling pathways. However, miRNAs are well known for their role in many physiological processes through post-transcriptional gene regulations. Here, we showed that this fundamental class of molecules, endowed with pleiotropic functions, is also necessary for oogenesis in medaka ovary. In particular, we showed that *miR-202* plays a key role in follicular recruitment and growth, and ultimately in the female reproductive success, as shown by the severe phenotype of *miR-202* KO fishes.

### **Mir-202-5p is the biologically active mature form in the ovary**

Our present results show that miR-202-5p is the predominant mature form processed from *miR-202* gene, while the miR-202-3p form is detected at much lower levels. This is consistent with existing data in which one miRNA form is biologically active, while the other is degraded. More specifically, our ISH experiments reveal that miR-202-5p is highly expressed in the somatic granulosa cells surrounding the oocyte. Consistently, recent transcriptomic studies in zebrafish reported either an increased expression of miR-202-5p during folliculogenesis or an increased expression in developing oocytes and unfertilized eggs (48)(49). Yet, it has also been claimed that *miR-202* could be expressed only in early medaka oocytes and absent at later stages, based on ISH experiments (16). Since our ISH did not reveal any expression of miR-202-5p above background levels in early oocytes, we presume that it is more likely accumulated during vitellogenesis in vitellogenic and/or post-vitellogenic oocytes, as suggested by the detectable expression in unfertilized eggs,

## ***Mir-202* is required for both male and female reproductive success, but not for sex determination**

Here, we observed that the inactivation of *miR-202* in medaka does not lead to any modification of the sex ratio, since mutant siblings give rise to 50% of adult males and 50% of adult females. This rules out the possibility of a key role of *miR-202* in sex-determination. It should however be stressed that the *miR-202* KO results in the sterility of both females and males. More particularly, when *miR-202* KO males were crossed with wild-type females, embryonic viability was dramatically reduced since most embryos were arrested during the first cleavage stages (st.4-5). To our knowledge, this phenotypic defect of male reproduction has never been reported before in fish, and it clearly indicates that *miR-202* is also required for spermatogenesis. This is in agreement with results obtained after *miR-202* KO in cultured spermatogonial stem cell in mouse, indicating a role in the control of the cellular proliferation/differentiation balance (27). Further studies are now required to unravel the precise role of *miR-202* in fish testis during spermatogenesis.

## **Females lacking *miR-202* produce eggs that cannot be fertilized**

In this study, we paid special attention to the severe phenotype displayed by *miR-202* KO females. The overall reproductive success of mutant females was reduced to 0.83 or, even more, to 0 viable eggs per clutch, compared to 15.3 viable eggs per clutch for wild-type females. This phenotype is the consequence of both a reduced fecundity (*i.e.* reduced number of spawn eggs) and reduced egg viability. Mutant females indeed produce a large proportion of eggs that cannot be fertilized, subsequently resulting in no embryonic development. During folliculogenesis, the somatic cells that surround the

growing oocyte (granulosa and theca cells) contribute to the formation of the chorion, and the micropyle, which is primordial for the egg fertilization (50). It is thus likely that *miR-202*, which is expressed in granulosa cells throughout folliculogenesis, contributes to the formation of a functional chorion and micropyle. However, we cannot totally exclude an additional role of *miR-202* in oocytes during the growth and maturation steps, given the possible accumulation of *miR-202* inside the oocyte.

## ***MiR-202* deficiency severely affects early folliculogenesis and female fecundity**

The very low fecundity of *miR-202* KO females strongly indicates that *miR-202* plays an important role in the oogenesis processes in the ovary, which was further investigated. One of the most remarkable features observed in mutant ovaries was the abnormal increased number of pre-vitellogenic follicles. Along with this phenotype, we observed a reduced expression of *gsdf* (a member of the TGFb family) and of the *foxl2* transcription factor. Both *gsdf* and *foxl2* are expressed in granulosa and are well known for their role as key regulators of early oogenesis/folliculogenesis (34)(51)(52). Downregulation of these factors thus confirms that *miR-202* likely controls the early development of granulosa cells (*i.e.* granulosa proliferation and/or differentiation) through the regulation of *gsdf* and *foxl2*, and ultimately leads to an impaired folliculogenesis. Such hypothesis is also supported by the down-regulation of downstream key genes, including steroidogenic genes (*star*, *cyp19a1a*, and *cyp17*) and the TGF-b family member *inhibin*. The formers are involved in estrogen synthesis in ovarian follicles, while *inhibin* plays a critical role during follicular development in zebrafish (53). Further

analysis of the proliferation and differentiation states of granulosa cells are needed to fully understanding of the role of *miR-202* during folliculogenesis. Of particular interest is also the down-regulation of *gsdf* in *miR-202* mutant ovaries. Along with its well-established key role in the male-determination in medaka, the GSDF factor is also thought to be necessary for normal ovarian development (54)(31). Indeed, *gsdf* inactivation not only impairs male differentiation, but also leads to a severely reduced female fecundity up to a total infertility for the most severe cases. In such mutants, the number of pre-vitellogenic follicles is abnormally high (31). Except the male-determination phenotypic defect, many features of the *gsdf* mutant are very similar to that observed for *miR-202* KO females, including the pre-vitellogenic follicles accumulation. We hypothesize that *miR-202* promotes *gsdf* expression in the ovary and boost its action on follicular development. In any case, such hypothesis remains to be confirmed and molecular mechanisms underlying the interaction between *miR-202-5p* and *gsdf* remain to be identified.

### ***Mir-202* knock-out impairs female meiosis**

The germinal cradle is composed somatic *sox9b*-expressing cells that surround mitotic and meiotic germ cells, as well as primordial oogonia barely engage into folliculogenesis (4). Our results show that *miR-202* is expressed in the germinal cradle, in a subset of *sox9b*-expressing cells surrounding primordial oogonia, which together likely correspond to primordial follicles. Interestingly, no modification of *sox9b* expression was observed in mutant ovaries, and previous studies in mouse have shown that *sox9* regulates the expression of *miR-202* in granulosa cells (55). It is thus possible that *miR-202* acts downstream of *sox9b* in medaka as well. However, molecular mechanisms that

regulate the expression of *miR-202* in follicles at later stages, in vitellogenic and post-vitellogenic follicles, remain to be determined since *sox9b* is not expressed at these stages.

We also observed, in juvenile ovaries, a down-regulation of the early meiotic oocyte markers *foxl3* and, to a lesser extent *sycp3*, even though no *miR-202* expression was detected in oocytes at this stage. Cellular interactions between germinal and somatic cells are thought to be important and to be mediated by several secreted factors (56)(57)(43). Consequently, any early defect of oocytes is likely to occur in the context of granulosa dysfunction (discussed above), including the onset of meiosis. One possibility is that *miR-202* depletion in the granulosa affects oocyte-somatic communications, as suggested by the down-regulation of KELCH proteins that have important functions in oocyte-somatic cell interactions in *drosophila* (43). This hypothesis is also supported by the dysregulation of the *npr1b* receptor and the intracellular effector *srgap3* of the SLIT/ROBO signaling pathway, which could both also mediate cellular communications in the ovary (46)(47).

### ***Mir-202*, a major player rather than a fine modulator**

As discussed above, a drastic reduction of the reproductive success was observed for both male and female medaka lacking *miR-202*, including a reduced female fecundity and the production of poor quality eggs that cannot be fertilized. This phenotype was confirmed using two mutant lines bearing different INDELs obtained with the same guide RNA. It is generally considered that the purview of miRNAs is more likely the maintenance of regulatory networks, by fine-tuning gene expression, rather than the establishment of key regulatory networks for developmental decisions or core

physiological processes. This concept is supported by the fact miRNAs KO are commonly associated with “modest” phenotypic effects, which are strongly exacerbated only under particular condition, as for example manipulations, stresses or disease conditions (28). This is in contrast with the drastic reproductive phenotype observed here for *miR-202* KO fishes. It is however possible that *miR-202* modulates a large networks of targets, which would have a synergistic effect on key regulatory pathways for folliculogenesis, such as *gsdf* (as discussed above), and ultimately leads to subfertile or sterile females. Nevertheless, the phenotypes observed in *miR-202*<sup>-/-</sup> fish are among the most severe observed after miRNA KO, and it would be very informative in the future to determine whether the drastic *miR-202* KO phenotype is an exception in the ovary.

## **A new look at oogenesis**

Surprisingly, the transcriptomic analysis performed in juvenile females, during the first reproductive cycle and before the occurrence of the first spawning, did not result in the identification of a large number of differentially expressed. It should however be stressed that among de differentially expressed genes were many genes that are crucial for steroidogenesis and reproduction, such as *star* and members of the *wnt* family (as discussed above). Despite these usual suspects, the transcriptome analysis also shed light on other genes such a genes of the *kelch* family that are less studied but believed to play an important role in oogenesis based on existing data in other animal species (58). Finally, the identification of genes that were previously not known to participate in oogenesis, such as *setd4*, *npr1b* and *srgap3*, could shed a new light on our understanding of this complex and coordinated biological process. This begs for further investigations that will greatly benefit from *miR-202*<sup>-/-</sup> fishes as a novel biological model.

## Conclusion

In summary, our results show that *mir-202* is a key miRNA involved in the regulation of follicular recruitment and growth. This provides the first functional evidence that microRNAs are necessary for the female reproductive success and in particular the regulation of female fecundity. Furthermore, the present study shed new light on the regulatory mechanisms that control the early steps of follicular development, which remain poorly understood to date. A further systematic *in vivo* functional analysis of other ovarian-predominant miRNAs should greatly increase our knowledge on the overall role of miRNAs in oogenesis and female fecundity in fish.

## Materials and methods

### Ethics statement

All experimental procedures were conducted in strict accordance with the French and European regulations on animal welfare recommendations and were approved by the INRA LPGP Animal Care and Use Committee.

### Medaka breeding and tissues collection

Adult medaka (*Oryzias latipes*) from the CAB strain and adults of the *Tg(sox9b::EGFP)* medaka line were raised at 26°C. Fishes were raised under a growing photoperiod regime until 3 months post-fertilization (12h light/ 12h dark) and under a reproduction photoperiod regime after 3 months post-fertilization (14h light/10h dark). For QPCR analysis, eleven different tissues/organs (brain, eyes, fins, gills, heart, intestine, kidney, liver, muscle, ovary and testis) were collected from wild-type and miR-202-/- fish. Embryos were collected at different stages (1-cell, 8-cell, stage 11/12, stage 17/18, stage

25/26, stage 29/30 and stage 39), according to the developmental table described by Iwamatsu *et al.* (59). For tissues/organs dissection, adult medaka fishes were euthanized by immersion in a lethal dose of tricaine at 30-50mg/L. All tissues/organs and embryos were immediately frozen in liquid nitrogen and subsequently stored at -80°C until RNA extraction. For histological analyses, ovaries were collected from wild-type females, fixed overnight in 4% paraformaldehyde (PFA) at 4°C and dehydrated in 100% methanol and stored at -20°C, before histological analyses.

## Establishment of the *miR-202* mutant medaka line

For the CRISPR/Cas9 knock-out analysis, the target genomic sequence was identified with the help of the ZiFiT online tool (<http://zifit.partners.org/ZiFiT/>) and using the medaka genome reference available on the Ensembl genome database (Ensembl gene: ENSORLG00000021212). A short sequence in the mature miR-202-3p was selected as followed: GG-(N)18-NN. Two inverse-complementary primers (Forward 5'-TAGGCATAAGGCATGGGAAAAT-3' and (Reverse 5'-AAACATTTTCCCATGCCTTATG-3') were annealed and cloned into the pDR274 vector (Addgene plasmid 42250) in the BsaI cloning site. The modified pDR274 vector was digested with DraI and the miR-202 specific guide RNA (mir202-sgRNA) was transcribed using the T7 RNA polymerase (P207, Promega). For the Cas9-RNA *in vitro* synthesis, the pCS2-nCas9n vector (Addgene plasmid 47929) was linearized with NotI and capped RNA encoding the Cas9 was transcribed with the mMessage mMachine SP6 Kit (AM1340, Life Technologies) following manufacturer's instructions. Cas9 and sgRNA were purified using phenol/chloroform and precipitated by Ammonium acetate. Cas9-RNA (100 ng/μL) and mir202-sgRNA (10 ng/μL) were co-injected into one-cell stage embryos. Injected

embryos were raised to sexual maturity and 10 fishes were genotyped to identified founder fishes (F0). Fishes harboring the same INDEL mutation (-7+3) were selected and outcrossed with wild-type fishes to obtain F1 heterozygous. Such outcrosses were performed at each generation in order to maintain the line. Homozygous fishes were produced for histological and molecular phenotyping analyses. A second line harboring another INDEL mutation (-8) was used in order to confirm the reproductive phenotype, but this line was not used for further histological and molecular analyses.

## Genotyping

Genomic DNA was extracted from a small piece of the caudal fin sampled from anesthetized adult fishes. Samples were lysed in 75mL of lysis buffer containing 1,25 M NaOH and 10 mM EDTA (pH 12) incubated at 90°C for 1h and were neutralized with 75mL of neutralization solution containing 2 M Tris-HCl (pH 5). To identify F0 founder fishes, genomic DNA around the expected mutation site was sequenced. For systematic genotyping of individuals of the established line, wild-type and mutant (INDEL -7+3) alleles were specifically detected by HID-PCR using specific reverse primers for each allele (S2 Table). The HID polymerase (Genaxxon bioscience, M3025.0250) was used with the following PCR conditions: 95°C for 2min; and 40 cycles of 95°C for 20 sec, 57°C for 15 sec and 72°C for 30 sec; and then 72°C for 7 min.

## Total RNA extraction

Frozen tissues were lysed with Precellys Evolution Homogenizer (Ozyme, bertin technologies) in TRI Reagent (TR118, Euromedex) and total RNA was extracted using the “nucleospin RNA” kit (740955, Macherey Nagel).

## Quantitative PCR

For expression analysis of mature miRNA forms, 20 ng of total RNA were reverse-transcribed (RT) using the TaqMan advanced miRNA cDNA Synthesis Kit (A28007, Applied Biosystems). Twenty fmol/ $\mu$ l of an external calibrator cel-miR-39-3p (478293\_miR, Life technologies) was added in the first step of the RT-Taqman PCR (polyA step) for 20ng of RNA. The cDNA was diluted (1:5) and universal primers (20x miR-Amp Primer Mix, 100029187, Applied Biosystems) were added in the last step of the RT reaction. The TaqMan QPCR was performed using 5  $\mu$ l of diluted cDNA, 1  $\mu$ l TaqMan Advanced miRNA Assay solution (CCU001S, Special Product Custom designed advanced miRNA assay, Life technologies) and 10  $\mu$ l Fast Advanced Master Mix (4444557, Applied Biosystems) in a total volume of 20  $\mu$ l. Specific modified probes complementary to *miR-202-5p* and *-3p* were designed as followed: *mir-202-3p* 5'<sub>FAM</sub>-AGAGGCATAAGGCATGGGAAAA-3'<sub>Quencher</sub> and *mir-202-5p* 5'<sub>FAM</sub>-TTCCTATGCATATACTTCTTTG-3'<sub>Quencher</sub> (Life technologies). QPCR was performed using the Step One Plus system (Applied Biosystems, USA) with the following conditions: 95°C for 20 sec; and 40 cycles of 95°C for 1 sec and 60°C for 20 sec. The relative expression of miRNA within a sample set was calculated from standard curve using Applied Biosystem StepOne V.2.0 software. All QPCR were performed in duplicates. MiR-26a (hsa-miR-26a-5p, A25576, ThermoFisher Scientific) or cel-miR-39-3p was used for normalization.

For mRNA and pri-miR-202 expression analysis, 2 $\mu$ g of total RNA was reverse-transcribed using the Maxima First Strand cDNA Synthesis Kit (K1671, ThermoFisher Scientific). The cDNA was diluted (1:20). The SyberGreen QPCR was performed using 4  $\mu$ l of diluted cDNA, 5  $\mu$ l of GoTaq QPCR Master Mix 2x (A600A, Promega) and 100 nM of each primer (S3 Table), in a total volume of 10  $\mu$ l. The QPCR was performed using the

Step One Plus system (Applied Biosystems, Foster City, USA) with the following conditions: 95°C for 2 min; and 40 cycles of 95°C for 15 sec and 60°C for 1 min. Standard curves were generated using five serial cDNA dilutions (from 1:2 to 1:32) of a pool of all samples. The relative abundance of target cDNA was calculated from standard curve using Applied Biosystem StepOne V.2.0 software. All QPCR were performed in triplicates and the *rpl7* gene was used for normalization.

## Microarray analysis

Gene expression profiling was conducted using an Agilent 8x60K microarray as previously described (60). Samples were randomly distributed on the microarray for hybridization. The data were processed using the GeneSpring software (Agilent v.14.5) using gMedianSignal values. The gene expression data was scale normalized and log(2) transformed before the statistical analysis. Corresponding data were deposited in Gene Expression Omnibus (GEO) (<https://www.ncbi.nlm.nih.gov/geo/>) database under the reference GSE111388. The differences between the groups were analyzed with unpaired t-test after application of minimum two-fold change filter with the significance level of 5 % ( $p < 0.05$ ) after Benjamini-Hochberg correction.

## Fluorescent *in situ* hybridization and immunostaining

For fluorescent *in situ* hybridization (FISH), fixed ovaries were embedded in paraffin and sections (9 µm thickness) were performed with a microtome (HM355, microm). An anti-sense Locked Nucleic Acid (LNA) oligonucleotide was designed and produced by Exiqon A/S to detect the mature miR-202-3p form. Since medaka and human miR-202-5p sequences are identical, we used the hsa-miR-202-5p miRCURY LNA™ miRNA detection probe to detect the mature medaka miR-202-5p form. A LNA™ Scramble-miR

probe (5'-GTGTAACACGTCTATACGCCCCA-3') was used as a negative control. All LNA<sup>TM</sup> probes were double-DIG labeled at both 5' and 3' ends. FISH was performed using the microRNA ISH Buffer Set (FFPE) Hybridization Buffer (ref. 90000, Exiqon), following the manufacturer's instructions with some modifications. Permeabilisation was performed for 7 min at room temperature using of Proteinase-K (10 mg/ml, P2308 Sigma). LNA probes were used at 20 nM at 53°C (30°C below the RNA T<sub>m</sub> °C) for 2 hours. Samples were then incubated overnight at 4°C with a rabbit anti-DIG HRP-conjugate antibody (1:500, Roche). For the GFP detection, a chicken anti-GFP (1/500, ref. ab13970, Abcam) was added at this step. The anti-GFP was first detected with a goat anti-chicken AlexaFluor488-conjugate antibody (1/500, ref. A11039, Life Technologies) for 1 hour at room temperature. Then, the anti-DIG-HRP antibody was detected with the TSA-Cy5 substrate (1:50, TSA<sup>TM</sup> PLUS Cy5 kit, NEL 745001KT, Perkin Elmer) for 15 min at room temperature. All pictures were taken under SP8 confocal.

## **Nuclear staining and image analysis**

Fixed ovaries were embedded in paraffin and median sections (7 µm thickness) were performed with a microtome (HM355, microm). Nuclei were stained with DAPI (0,1 µg/ml) at room temperature for 15 minutes in the dark. Median sections were washed 1h in PBS at room temperature. Images of whole sections were acquired with a nanozoomer (HAMAMATSU). For quantitative image analyses, individual oocyte's area was measured using an image analysis software (Visilog 7.2 for Windows). Based on DAPI staining intensity, the nucleus were segmented then the inner part surround by the nucleus and corresponding to oocytes were individually measured. Pictures were taken under a Nikon AZ100 microscope and DS-Ri1 digital camera.

## ACKNOWLEDGMENTS

We thank the INRA-LPGP fish facility staff, and especially Cecile Duret, for fish rearing and husbandry. We also thank the University of Rennes 1 H2P2 facility for the use of the slide scanning nanozoomer.

## Founding

This work was funded by the TEFOR project (Agence National de la Recherche, ANR-II-INBS-0014, <http://www.agence-nationale-recherche.fr/investissements-d-avenir/projets-finances/>). VT received the funding. This work has also been supported by the ERA-Net COFASP (COFA) AquaCrispr project (Agence National de la Recherche, ANR-16-COFA-0004, <http://www.agence-nationale-recherche.fr/suivi-bilan/editions-2013-et-anterieures/environnement-et-ressources-biologiques/era-net-cofasp-cooperation-in-fisheries-aquaculture-and-seafood-processing/>). JB received the funding. The funders had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

## Author Contributions

SG performed histological and molecular analyses, participated in mutant fish phenotyping, data analysis and manuscript writing. JBu participated in histological analyses. AB participated in generating the mutant line and in tissue collection and RNA extraction. LH participated in reproductive phenotype analysis. ALC performed the microarray analysis. JM performed bioinformatics analyses. VT and JBo conceived the

study, participated in data analyses and wrote the manuscript. VT supervised and coordinated the study. All authors read and approved the final manuscript.

## **Additional information**

### **Supplementary information accompanies this paper**

### **Competing financial interests**

The authors declare that they have no competing interests.

### **Availability of data and material**

The microarray expression data are available from the gene expression omnibus (GEO) database (accession # GSE111388, <http://www.ncbi.nlm.nih.gov/geo/>).

## Supporting information

**S1 Fig.** FISH on ovarian section performed with a scramble control probe

**S1 Table.** Differentially expressed genes obtained through a microarray analysis

**S2 Table.** Primers used for HIDI-PCR

**S3 Table.** Primers used for QPCR

## Figure captions

**Figure 1: Expression profile of miR-202-5p in adult tissues and during embryonic development.** (A) Sequence and secondary structure of the pre-miR-202. miR-202-5p is in red and miR-202-3p in blue. (B) Tissue distribution of miR-202-5p in eleven adult tissues obtained by TaqMan QPCR (Box plots, n=8, the ends of the boxes define the 25th and 75th percentiles; a line indicates the median and bars define the 5th and 95th percentiles). Cel-miR-39-3p was used as an external calibrator for normalization. (C) Expression profile of miR-202-5p during embryonic development. Pools of embryos at the same stage were used for TaqMan QPCR. *ns*, no significant difference (Student t-test). #expression levels not significantly different from the background signal.

**Figure 2: Expression of miR-202-5p and miR-202-3p in the ovary.** Fluorescent *in situ* hybridizations (FISH) were performed on sections of ovaries from juvenile and adult medaka females. MiR-202-5p (A, B) and miR-202-3p (C, D) were detected with specific LNA miRNAs detection probes (in red). Ovaries of adult females were dissected from the transgenic medaka line *Tg(sox9b::EGFP)*. The somatic GFP+ cells of the germinal cradle, including early granulosa cells, were immunodetected (in green) (B, D). Nuclei are stained with DAPI (in blue). (A') A magnified view of the juvenile ovarian

section. **(B', B'' and B''')** Magnified views of the adult ovarian section. Mir-202-5p is detected in granulosa cells of follicles at all stages in both juvenile and adult ovary (arrowhead), but not in the theca cells (arrow). **(B''')** MiR-202-5p co-localize with GFP in early granulosa cells surrounding pre-vitellogenic follicles. **(C, D)** Mir-202-3p is not detected in ovaries from juvenile and adult fishes. PreV, pre-vitellogenic follicle; V, vitellogenic follicle; PV, post-vitellogenic follicles. Scale bars: 500  $\mu$ m (A-D), 50  $\mu$ m (A', B', B'') and 20  $\mu$ m (B''').

**Figure 3: Analysis of the reproductive phenotype of *miR-202*<sup>-/-</sup> adult fish.** **(A)** Genomic regions of wild-type and mutant fishes showing the INDEL mutations (-7+3) inserted in the miR-202-3p sequence using CRISPR/Cas9 genome engineering. **(B)** Expression levels of the pri-miR-202 and miR-202-5p forms in the ovaries of wild-type and homozygotes females (*miR-202*<sup>-/-</sup>) were measured by QPCR. **(C)** Spawning frequency of mutant and wild-type females were monitored during ten days. Subfertile females (irregular spawning) and sterile females (only one spawning) represent respectively 85% and 15% of all analyzed females. **(D)** Number of eggs per clutch spawned by wild-type or subfertile females when mated with wild-type or mutant males. **(E)** Embryonic viability of spawn eggs measured by the percentage of eggs that are fertilized and that develop correctly. **(F)** Representative pictures of eggs from the different crosses of wild-type and mutant males and females. Mean values ( $\pm$  SEM) are displayed on the graphs. \* indicates expression levels that are significantly different (Mann Whitney test,  $p < 0.05$ ). Different letters indicate a significant difference, as determined by a one-way ANOVA test (Tukey's post hoc test). #expression levels not significantly different from the background signal.

**Figure 4: Quantitative image analysis of *miR-202*<sup>-/-</sup> juvenile ovaries.** (A) Median sections of ovaries from juvenile wild-type and *miR-202*<sup>-/-</sup> fishes. All nuclei are stained with DAPI (in blue). Image sections were automatically segmented. (B) Section area, mean follicle diameter and follicle number automatically determined. (C) Size distribution of follicles on sections. The number of small follicles (50-100  $\mu$ m) is significantly higher compared to wild-type, while the number of follicles in the larger diameter class (200-350  $\mu$ m) tends to decrease. Box plots are displayed on graphs for wild-type (n=7) and *miR-202*<sup>-/-</sup> (n=8) juvenile females (in red and green, respectively). The ends of the boxes define the 25th and 75th percentiles; a line indicates the median and bars define the 5th and 95th percentiles. Individual values are shown for the graphs of panel B. Asterisks indicate significant differences (\*  $p < 0.05$  and \*\*  $p < 0.01$ , Mann Whitney test). Scale bar: 500  $\mu$ m.

**Figure 5: Quantitative image analysis of *miR-202*<sup>-/-</sup> adult ovaries.** (A) Median sections of ovaries from wild-type, sterile and subfertile mutant females. All nuclei are stained with DAPI (in blue). Image sections were automatically segmented. (B) Section area, mean follicle diameter and follicle number automatically determined. (C) Size distribution of follicles on sections. In ovaries from sterile females, the number of large follicles (>400  $\mu$ m) is significantly reduced, while small follicles (<100  $\mu$ m) tend to accumulate. In the ovary from subfertile females, the number of medium follicles (100-400  $\mu$ m) is significantly reduced, but small size follicles (<100  $\mu$ m) do not accumulate. Box plots are displayed on graphs for wild-type (n=10), *miR-202*<sup>-/-</sup> subfertile (n=10) and *miR-202*<sup>-/-</sup> sterile (n=4) adult females (in red, green and blue, respectively). The ends of the boxes define the 25th and 75th percentiles; a line indicates the median and

bars define the 5th and 95th percentiles. Individual values are shown for graphs of panel B. Asterisks indicate significant differences (\*  $p < 0.05$  and \*\*  $p < 0.01$ , Mann Whitney test). Scale bar: 500  $\mu\text{m}$ .

**Figure 6: mRNA expression profiles of ovarian genes in *miR-202*  $-/-$  females.** Gene expression levels in wild-type and ovaries from juvenile females were obtained by QPCR. (A) Genes expressed in the somatic germ-cell supporting cells. (B) Genes expressed in primary oocytes within the germinal cradle. (C) Genes that belong to the WNT and KELCH families. (D) Dysregulated genes that have never been previously described as molecular players of oogenesis. Expression levels were measured in triplicates. Box plots are displayed on graphs for wild-type (n=6) and *miR-202*  $-/-$  (n=5) juvenile females. The ends of the boxes define the 25th and 75th percentiles; a line indicates the median and bars define the 5th and 95th percentiles. Individual values are shown. The *rpl7* gene was used for normalization. Asterisks indicate significant differences (\*  $p < 0.05$  and \*\*  $p < 0.01$ , Mann Whitney test).
