Isotopic discrimination against  $^{13}\text{C}_2$  during photosynthesis ( $^{13}\Delta$ ) causes the overall  $^{13}\text{C}$  depletion of the terrestrial biosphere compared to the atmosphere.  $^{13}\Delta$  varies in response to environmental variables that influence photosynthetic gas exchange. For  $\text{C}_3$  plants,  $^{13}\Delta$  mainly reflects the balance between the  $\text{CO}_2$  supply to and the  $\text{CO}_2$  demand by the carboxylation sites, but it is, to a smaller extent, also influenced by carbon isotope fractionations occurring during mitochondrial and photo-respiration. Understanding and predicting  $^{13}\Delta$  variability has gained relevance for  $\text{CO}_2$  flux partitioning on the global and the ecosystem scale, for tree ring analysis or for insights into plant/soil dynamics. Estimates of  $^{13}\Delta$  are commonly obtained by combining carbon isotope measurements of plant-derived organic matter or air profiles with  $^{13}\Delta$ -models. In contrast, direct, gas exchange-based measurements of  $^{13}\Delta$  under field conditions are sparse, due to the technical deployment involved. Hence, we have little experimental verification of diurnal and seasonal variabilities of  $^{13}\Delta$  and their relation to environmental drivers. We further lack a thorough field-based evaluation of the Farquhar et al. (1982)  $^{13}\Delta$ -model. Here, we present continuous, hourly field measurements of  $^{13}\Delta$  of *Fagus sylvatica* L. branches, conducted with three custom-made open branch bags and a laser spectrometer for  $\text{CO}_2$  isotopologue measurements (QCLAS-ISO, Aerodyne Research Inc.). Data from two field campaigns (in total 38 and 60 days) in a mature, temperate mixed-deciduous forest in Switzerland during August / September 2009 and 2010 are shown. We observed a high diurnal variability of  $^{13}\Delta$ , with average diurnal amplitudes of  $\approx 10\text{‰}$  and maximum diurnal amplitudes of  $\approx 20\text{‰}$ . Highest  $^{13}\Delta$  were generally observed during dawn and dusk, and lowest  $^{13}\Delta$  during midday. Morning and afternoon  $^{13}\Delta$  commonly displayed intermediate values. Day-to-day variations were summarized with flux-weighted daily means of  $^{13}\Delta$ , which ranged from  $15\text{‰}$  to  $23\text{‰}$  in 2009 and from  $18\text{‰}$  to  $29\text{‰}$  in 2010. If trees were not water-limited, branch gas exchange, and hence  $^{13}\Delta$ , appeared to be mainly driven by changes in incident PAR. Woody tissue  $\text{CO}_2$  efflux was measured with two independent approaches to assess its potential bias on branch bag measurements. We estimated that its contribution to branch net  $\text{CO}_2$  assimilation was  $< 0.1 \mu\text{mol m}^{-2} \text{s}^{-1}$  per total leaf area during the time of our field campaigns.

Using data from the 2010 field campaign only, we explored the applicability of the comprehensive ( $^{13}\Delta_{\text{comp}}$ ), the simplified ( $^{13}\Delta_{\text{simple}}$ ) and the revised ( $^{13}\Delta_{\text{revised}}$ ) versions of the Farquhar et al. (1982) - model for predicting observed diurnal and day-to-day  $^{13}\Delta$  variabilities.  $^{13}\Delta_{\text{comp}}$  predicted the mean diurnal variability of  $^{13}\Delta$  much better than  $^{13}\Delta_{\text{simple}}$  (RMSE<sub>simple</sub>  $\approx 3.4$ ; RMSE<sub>comp</sub>  $\approx 2.5$ ). Furthermore,  $^{13}\Delta_{\text{comp}}$  was more suitable than  $^{13}\Delta_{\text{simple}}$  for predicting flux-weighted daily means of observed  $^{13}\Delta$ . For model calibrations, a Bayesian inference approach was used. This approach allowed us to reliably quantify uncertainties in the model parameter estimation and to reveal the amount of model-relevant information present in our field dataset.
