What is the cost of low participation in French Timber auctions?

Raphaële PRÉGET (INRA)[§]
Patrick WAELBROECK (ENST)[¥]

August, 2010

Abstract

How much is the timber from public forests worth? How can the Public Forest Service define a fair market price for standing timber lots? What is the cost of low participation in French timber auctions? To estimate the value of a timber lot we adopt the transaction-evidence appraisal approach using data from timber auctions in Lorraine (Eastern France) accounting for the facts that: *(i)* the seller's reserve prices are secret, *(ii)* there remain many unsold lots, and *(iii)* the number of bidders varies from one auction to another. Taking into account the endogenous participation in our hedonic price equation for the highest bid, we estimate that, compared to lots that receive two bids, the highest bid is 22% lower when there is only one bid and 37% higher when there are three or more bids.

Key words: Timber auctions, hedonic prices, sample selection, endogenous participation.

Code JEL: C11, C15, C34, C35, C63, D44, L73.

1 Introduction

Fifty percent of hardwood timber lots in public timber auctions in Lorraine (Eastern France) received zero, one or only two bids and 42% of lots have not been auctioned (Costa and Préget, 2004). Moreover, 40% of auctioned lots were sold under the seller's secret reserve price. Low participation is a real issue in French public timber auction. But more generally, how much is the timber from public forests worth? How can the Public Forest Service define a fair market price for standing timber lots? Answering these questions is challenging. First, it is difficult to refer to production costs. Indeed, a forest takes time to grow and expand. Timber supply is more a harvesting decision based on silvicultural motives and related to the management of a renewable natural resource, than just a question of wood production. Secondly, the seller (the Public Forest Service) wants to maximize sales receipts, but also has other objectives, such as securing the timber supply to the wood local industry at a price that allows them to remain competitive on international markets and/or against other industries (steel, aluminum, etc.). Thus, the objectives of the seller might be multiple and contradictory. Third, standing timber is different from perishable goods. The optimal time for harvesting might have passed if the lot remains unsold for many years, but the trees continue to grow and the forest still offers other values (recreation, carbon sequestration, biodiversity, water filtration, ...) that are difficult to take into account when defining the value of a timber lot. To sum up, it is difficult for the seller to evaluate her own reservation value for a lot in standing timber sales.

Yet, even if the Public Forest Service uses an auction system to set the selling price, the sales director needs to set a relevant reserve price for each timber lot that he wants to sell. Given that assessing the value of a standing timber lot is challenging, the seller needs to refer to demand factors such as: lot quality, species composition, lot location, harvesting conditions, etc. In this article, we use the so called "transaction evidence appraisal" (TEA) reduced form method, *i.e.* we estimate timber value from market prices obtained during past timber auctions in France.

Most French timber sales are sequential first-price sealed-bid auctions of heterogeneous lots. Heterogeneity in the product is probably the most important feature of standing timber sales. Lots differ from each other with respect to volume, composition, location, harvesting conditions, etc. (inter lots heterogeneity). But a lot is also composed of trees of different species and qualities (intra lot heterogeneity). These inter- and intra-lot heterogeneities raise various questions about the valuation of the lots that are put on sale and about their optimal composition. Heterogeneity of timber lots makes the hedonic price function approach useful in order to infer appraisal value since many characteristics may influence the stumpage price. The hedonic price method is based on the implicit price of each characteristic and determines how the market values a lot as a set of characteristics. This empirical approach to timber characteristics could help the Forest Service to design the auctioned lots (the size, the species composition, etc.) and to determine her reserve price.

There are two problems that arise when we analyze timber auction data sets. Both arise from the endogenous participation of the bidders in the auctions. First, there are many lots for which there is no bid and there are good reasons to think that this outcome is not random: bidders may not bid on timber lots that are of bad quality or have difficult harvesting conditions, etc. It is important to note that in French timber auctions, the seller does not announce any reserve price. The seller might withdraw the lot if she thinks the highest bid is too low, but the reserve price is kept secret before the auction. Thus, the lack of bids cannot be explained by a reserve price that is set too high, since no minimum amount is required to bid for a lot. Of course, lots with no submission remain unsold. However, we have to take lots without bids into account in the estimation procedure in order to prevent a possible sample selection bias. Secondly, when there are bids submitted for the lot, the degree of competition varies from one auction to another. According to the independent private values auction model, the number of bidders has a positive impact on the bidding strategies in first-price auctions. Indeed, bidders bid more aggressively when the number of bidders increases. Moreover, there are many auctions with only one bidder. This special case needs to be analyzed with caution. Remember that the number of bids cannot be explained by the value of the reserve price here, so it is sensible to think that the number of bidders is driven by the characteristics of the lot. In other words, the number of bidders has to be included in the hedonic price equation as an endogenous explanatory variable.

From an econometric point of view, the main problem is related to the correlation between unobservable variables that determine the participation process and the auction result. We solve this challenge by specifying a 3-equation model: equation (1) defines the probability that there is no bid, equation (2) determines among submitted lots the degree of competition, and equation (3) is the hedonic price equation that explains the auction result. We estimate parameters of this system of simultaneous equations using a Bayesian Monte Carlo Markov Chain (MCMC) simulation algorithm, which simplifies inferences in latent discrete variables models.¹

Our empirical work contributes to the literature on timber value appraisal by explicitly modeling the fact that the seller's reserve price is not announced. This is the main difference with the existing stumpage appraisal literature (discussed in the next section) that uses the Tobit two-stage procedure. Indeed, we cannot explain bidders' participation by the level of the reserve price. In this article, bidder participation directly depends on the characteristics of the timber lot. Secondly, we take into account the fact that bidders' participation is endogenous and we measure the cost of low competition in timber auctions.

In the next section, we specify our objective and our empirical approach through a survey of the literature on timber auctions and timber appraisal. Section 3 describes the institutional framework of French public timber auctions and the data set. The methodology is detailed in section 4 and section 5 presents the results. Section 6 concludes our research.

2 Timber appraisal

It is not straightforward for the seller to know below which price she should not sell a timber lot, even when she sees the highest bid. Theoretically, the seller's (reservation) value v_0 corresponds to the price under which the seller would get no profit from the transaction. That value is usually supposed to be exogenous, contrary to the reserve price which is strategically

¹ See Poirier and Tobias (2007) for instance for a general introduction on this topic. The idea is to replace methods based on maximum likelihood that often do not converge in complicated settings.

chosen by the seller. The seller commits not to sell the good below the reserve price. Of course, if the seller has perfect information on her private value v_0 , the reserve price should not be lower than v_0 . But actually, we claim that the seller does not perfectly know her v_0 when the auction takes place. We can see v_0 as the best expected price that the seller could obtain in a future sale. That value depends on many features. For example, it depends not only on future global market conditions and macro variables, but also on how the market is valuing each characteristic of the lot. It is with respect to the latter feature that we want to improve timber appraisal. Our objective is to use the results of past timber auctions to build a hedonic price equation.

We propose a reduced form procedure based on timber transaction evidence appraisal (TEA) to estimate the value of a timber lot and the cost of low participation in French timber auctions. The TEA method relies on the results of past timber sales, usually auctions, for predicting stumpage prices.² Unsold timber lots were not considered in early regression-based models (e.g. Jackson and McQuillan, 1979, McQuillan and Johnson-True, 1988). Prescott and Puttock (1990) and Puttock, Prescott and Meilke (1990) propose a standard hedonic price function to forecast stumpage prices in Southern Ontario timber sales; there was no unsold lots in their data. Buongiorno and Young (1984) modeled winning bids using OLS conditional on timber auctions that received at least two bids. However, as Huang and Buongiorno (1986) argued, the fact that some timber lots remained unsold is important market information. Thus, the following transaction evidence appraisal models include this market information to prevent biased predictions of market values. Since the reserve price is known and announced before the auctions in U.S. timber sales, it is assumed that the reserve price explains why some lots are not sold. Therefore, to take into account unsold lots, censored regressions (Tobit models) have been conducted (Huang and Buongiorno, 1986). Niquidet and van Kooten (2004) do not have sufficient information on no-bid auctions (or non-submitted lots), so they seek to predict a fair market value of standing timber in British Columbia using a two-stage truncated regression procedure.

² Before the TEA method was introduced in the 1980's, the residual value approach was used. The residual value mainly represents the price of all the products likely to result from a particular timber lot, subtracting all the processing costs. (Nautiyal, 1980)

Beyond the treatment of unsold lots, the number of bidders also appears as an important variable in the estimation of the winning bid in stumpage appraisal literature. Indeed, the degree of competition in auctions has an impact on the bidding strategies. Participants do not necessarily know the actual number of bidders, but they bid according to the expected or potential competition (Brannman 1996). Many studies on timber auctions such as Johnson (1979), Hansen (1986), and Sendack (1991) empirically support the auction theory prediction that there is a positive relationship between the number of bidders and the value of the highest bid. Sendack (1991) explicitly examines the impact of the number of bidders on the winning bid by including a transformation of the number of bids submitted as an explanatory variable. Assigning a dummy variable to each number of bidders ($n = 1, n = 2, \dots, n = 11$), Brannman, Klein and Weiss (1987) obtained estimated coefficients that support first-price auction theory: bid shading is decreasing with the number of bidders. None of these studies endogenize participation. However, to use stumpage appraisal models as predictive tools it is necessary to endogenize the actual number of bidders. Examining the impact of the (announced) reserve prices in sealed-bid Federal timber auctions, Carter and Newman (1998) endogenize the number of bidders in a simultaneous-two-equations Tobit framework, but the expected number of bidders is determined strictly by the reserve price.³ Of course, this model does not fit French timber auctions since the reserve price is secret.

Parallel to the reduced form approach, there is a recent but important and growing literature on structural econometrics of auctions. See for example Laffont and Vuong (1996), Perrigne and Vuong Q. (1999), Athey and Haile (2002), Paarsch and Hong (2006) for surveys. The aim of this highly technical and sophisticated literature is to estimate the structural parameters of a well defined theoretical auction model so as to simulate new auction formats. The main drawback of this approach is that a tractable theoretical model needs first to be solved at least partially. Auction theory has developed a great deal during the last three decades, nevertheless our understanding of real auction sales is far from complete. Although timber auctions have many special features that distinguish them from most theoretical auction models, some articles in the structural econometrics of auctions literature rely on timber auction data: Paarsch (1997), Baldwin, Marshall and Richard (1997), Li and Perrigne (2003), Athey, Levin and Siera (2004), and Campo, Guerre, Perrigne and Vuong (2006),

³ They treat the number of bidders as a continuous variable.

among others. The main objective of these articles is to compare the results of different auction formats. In most structural timber auction studies, as in our data, there is a variable called the seller's estimate or the appraisal value. Usually that value is found to be a summary of all the other variables (such as quality, species composition, harvesting condition, etc). Most papers use only that variable to take into account the object heterogeneity between auctions. In contrast, we want to improve on the appraisal value of the seller. Therefore, we will focus on all other variables that might influence her reservation value. Beside, the purpose of a hedonic price model is also to discover some specific patterns in the data that can be used by analysts to develop suitable structural models.

We propose to estimate a hedonic price function based on the highest bids. The highest bid of an auction is not necessary a winning bid (and thus a market price) since the seller might withdraw the lot if she believes that the highest bid is too low. However, we choose to estimate the highest bid and not the sale price because the sale price is not independent from the seller's decision (because of the secrete reserve price) and thus is less informative about market demand.⁴

3 Data on French timber auctions

Competitive bidding is widely used in timber sales in France. In particular, the French National Public Forest Service (ONF⁵) uses first-price sealed-bid auctions to sell timber from public forest. Timber auctions of ONF, which represent 40% of the timber sold each year in France, generally concern standing timber. The auction mechanism seems to be the best way to determine an "objective" or a "fair" market price for such a heterogeneous product. Before presenting the dataset on fall timber auctions in Lorraine conducted by ONF in 2003, we describe the institutional framework of French timber auctions.

⁴ There is a difference between the highest bid and the private value of the highest bidder. According to auction theory, buyers in first-price sealed-bid auctions do not bid their valuation. However, we do not attempt to infer the bidders' private value here. Our aim is more to build a price equation for a fair market price based on lots characteristics.

⁵ ONF stands for Office National des Forêts.

Timber auctions are sequential auctions of heterogeneous goods since many different lots (usually more than one hundred) are put on sale one after the other; the result of the auction of a lot is given before the next lot is put on sale. The first lot is usually randomly drawn, next the auctioneer follows the catalogue order. The sale catalogue details all the lots and is available to the bidders before the sale.

Lots are heterogeneous (different from one another), but they are also made up of heterogeneous wood. In particular in standing timber sales, a lot may contain many species of different diameter and of different quality. Auctioning such a product raises the problem of the optimal lot composition. The successive auctions correspond to different lots, but lots might be interrelated. Some lots may be close substitutes while others may present synergies. For example, it may be only profitable for some buyers to harvest two or more lots that are close to each other.

Taking into account the heterogeneity of the lots raises practical issues. Potential buyers visit the lots that they intend to buy, so as to infer their own private value for the lot. From a buyer's point of view, the estimated value of a lot is different than from the seller's point of view. Buyers have information on harvesting costs, on what they will produce with the wood and at what price they will be able to sell their products. It is therefore easier for them than for sellers to estimate their reservation value for a given lot. Therefore, as in most timber auction models, we believe that each bidder knows his private reservation value for a particular lot, especially for hardwood lots. That value depends on the characteristics of the lot, but may also depend on his inventory (*i.e.* on which lots the buyer already bought, and on whether he still needs wood). Nevertheless, bidders have to prospect 5 to 10 times as many lots as they intend to buy since they are not guaranteed to obtain the lots that they want. This leads to non-negligible prospecting costs for the bidders.⁶ These search costs, which are linked to the heterogeneity of the product, are wasteful from a social perspective. Reducing the cost of preparing a bid in timber auctions may increase the number of bidders. Actually, Gal, Landsberger and Nemirovski (2007) analyse participation to an auction as part of equilibrium. In an auction model with bi-dimensional distribution of types and endogenous

⁶ See Leffler and Rucker (1991) and Leffler, Rucker and Munn (2000) on transaction costs in timber auctions.

distribution of participants, they show that it can be profitable for the auctioneer to partially reimbursing bidders for the cost of preparing bids.

As mentioned above, and contrary to North American timber auctions, the reserve price of the seller is not announced in French public timber auctions. It is kept secret. This singular practice has been studied in the literature, but is difficult to justify theoretically. Elyakime, Laffont, Loisel and Vuong (1994) show in an independent private value auction model that the seller is always better off announcing her reserve price. Nevertheless, the practice of a secret reserve price is sometimes justified either by the fact that announcing a reserve price reduces the participation of the bidders or by a common value component (Vincent, 1995). Risk aversion is also mentioned to justify a secret reserve price (Li and Tan, 2000). A lack of competition for some lots and ONF's willingness to maintain a reasonable timber price may also explain this practice. Finally, a secret reserve price may be used to prevent collusion between bidders at the reserve price. When the reserve price is not announced, the optimal secret reserve price should be equal to the seller's reservation value v_0 .

We believe that the seller prefers not to announce and commit to any reserve price mainly because she does not know her reservation value at the auction time as claimed in the previous section. Indeed, a (secret) reserve price is reported for each lot in the database, but this price is not the seller's reservation value since many auctioned lots (about 40% in our data set) are sold under this reserve price (which should theoretically be equal to the seller's private valuation v_0). This means that the French public Forest Service decides to sell or not a lot at the last moment and does not commit to any reserve price before the auction. So, the seller uses the bids to adjust her valuation v_0 of the lot. With this privilege, the seller keeps a certain flexibility to manage the sale, but that practice may be costly for the seller from an auction theoretical point of view. Without firm and credible commitment, ONF may lose a part of the benefit of an auction. If the bidders anticipate that the seller can modify the rules of the game, then they will modify their bidding strategy, which may lower the efficiency of the bidding mechanism. Nevertheless, the fact that the seller updates her reserve prices shows her difficulty to assess her value v_0 of a lot. Hence, announcing a reserve price might have negative consequences if the model used to set reserve prices is mis-specified. Indeed, a reserve price set too high can result in no bids, while a reserve price set too low may result in too much bid shading especially since the number of bidders is usually low in timber auctions.

The dataset we use is part of the data collected by Costa and Préget (2004). It relies on the auction results of the ten fall 2003 timber sales of Lorraine, a Region of the eastern part of France. A total of 2262 lots were put on sale. Since there are many differences between hardwood and softwood valuations, we select only pure hardwood lots, i.e. lots that are composed of more than 99% of hardwood. Between September 9th and October 28th 2003, 1205 hardwood lots have been put on sale. Lots may be very heterogeneous and made up of many species. The Herfindahl index is used to measure intra lot heterogeneity.⁷ Out of the 1205 hardwood lots put on sale, only 52% of the lots are put on sale for the first time; thus 48% of the lots correspond to previously unsold lots.

At the end of the auctions, lots may be classified according to the auction results. A lot sold during the auction is said to be “auctioned”, whereas the others are called “unsold lots”. The percentage of unsold lots is 42% and shows a relatively difficult wood market environment in the Lorraine area during that period. It is useful to distinguish between lots that got one or more bids but have nevertheless been withdrawn by the seller and lots that got no bid at all, referred to as the “no bid” category. Table 1 presents sale results according to the number of bidders. In the data there are up to 13 bids for a lot, but the most frequent case is when there is only one bid.

Table 1. Timber auction results

Number of bids	0	1	2	3 and more	Total	
Auctioned lots	-	112 (9%)	106 (9%)	477 (40%)	695 (58%)	
Unsold lots	Withdrawn lots	-	115 (10%)	77 (6%)	126 (10%)	318 (26%)
	No bid	192 (16%)	-	-	-	192 (16%)
Total number of lots	192 (16%)	227 (19%)	183 (15%)	603 (50%)	1205 (100%)	

In our empirical application, we first propose to distinguish timber lots which received no bid and lots for which we observe at least one bid. Second, among the submitted lots, we distinguish 3 categories depending on the level of competition (i.e. the number of bidders):

- i) there is no competition: 1 bid,

⁷ The Herfindahl index is the sum of the square volume proportion of each species. Here the number of species is limited to 7, then the Herfindahl index varies from 0.14 to 1. The more homogeneous the lot, the closer is the index to one.

- ii) there is limited competition: 2 bids,
- iii) there is strong competition for the lot: 3 bids or more.

The database of Costa and Préget (2004) includes more than one hundred variables that represent a large part of the information available in the catalogues. It also includes private information from ONF (harvesting conditions, quality of the lot, secret reserve price), data about the auction results (the number of bids, the auctioned prices) and computed data such as the Herfindahl index. This database is particularly rich. Moreover, it is exhaustive since it contains all the standing timber lots from public forests put on sale in the region during the fall of 2003. Nevertheless, the data set does not contain any information about the bidders. The following two tables give summary statistics of variables used in our econometric study.

Table 2. Descriptive statistics for binary variables

Variable	%
No restrictions	37.18
Cutting	
arranged cutting	52.70

Table 3. Descriptive statistics for continuous variables

Variable	Mean	Std. Dev.	Min	Max
Surface (in hectare)	12.41	10.38	0.20	104.04
Number of trees	238.27	205.63	21	2259
Number of poles	267.07	663.76	0	11366
Herfindahl index	0.6007	0.1949	0.3337	1.0000
Stem volume of the mean-tree	1.0623	0.7314	0.0596	4.7190
Oak volume without crown	94.51	115.98	0	859.98
Beech volume without crown	136.83	164.09	0	1365.80
Other hardwood volume without crown	67.66	97.25	0	838.60
Crown hardwood volume	166.62	153.64	0	1196.47
Coppice volume	0.33	5.39	0	153.83
Relative order of the auction	0.50	0.29	0	1

All continuous variables are defined in logs except variables in percentage such as the Herfindahl index, the variable used to give the relative order of the auction in the sale and the stem volume of the mean-tree. Thirty six percent of the auctioned lots are sold at a price lower than the seller reserve price. These figures show that the seller does not commit to a credible reserve price and takes her decision to accept or not the highest bid at the last moment. Thus, the “a priori” reserve price of our data set has not a clear significance.

4 Methodology

Participation in timber auctions raises two econometric problems. First, many lots receive no bid and thus remain unsold at the end of the sale. Secondly, the number of bidders in an auction has an impact on the result of the auction: it makes a big difference if there is only one bidder (no competition) or if there are two or more bidders that compete for the same lot.⁸ Nevertheless, participation depends on the characteristics of the lots and thus is endogenous from an econometric point of view. We propose a reduced form econometric methodology that simultaneously deals with non-submitted lots (sample selection) and an endogenous number of bidders in the hedonic price function. We explicitly model participation by constructing J categories; but as announced before, we will consider 3 categories in our application: 1 bid, 2 bids, and 3 bids or more. We explain the intensity of participation by the characteristics of the lots in an ordinal probit framework.

We propose a Bayesian Monte Carlo Markov Chain (MCMC) sampling algorithm. We know that classical maximum likelihood procedures might be unreliable, even when we analyze the issues of sample selection and endogenous explanatory variable separately. We are not aware of any study that deals with both issues at the same time as it would require three correlation coefficients to estimate. The existing maximum likelihood estimation procedures (such as simulated maximum likelihood) do not perform well with multiple correlation coefficients and sample selection (see Waelbroeck, 2005). This justifies our Bayesian algorithm that is more reliable to produce robust correlation coefficients. The idea is to simulate the (latent) variables that determine the participation outcomes, which greatly simplifies the analysis of the joint posterior distribution of the parameters.⁹ We propose a slightly different MCMC algorithm for the sample selection part of the model than Van Hasselt (2005). We write the latent model as a SUR model with an unequal number of observations; and thus inference on the coefficients of the observed equation only relies on observations that are not censored.

⁸ Even when there is only one bidder, the submitted bid can not be too low because it has to reach the secret reserve price of the seller in order to become a winning bid.

⁹ Indeed, latent variables can be simulated and, conditional on these variables, the model is a simple Seemingly Unrelated Regression (SUR) model that is easy to deal with. We use a Metropolis step to draw from the conditional posterior distribution of the elements of the covariance matrix of the unobservable variables.

Despite the importance of the issue of sample selection with endogenous variables, we are not aware of a study that deals simultaneously with these two issues. On the one hand, the problem of sample selection has been widely analyzed in the econometrics literature starting with the seminal work of Heckman, who proposed a method (Heckit) to correct sample selection bias. Van Hasselt (2005) has proposed a Bayesian Monte Carlo Markov Chain (MCMC) algorithm to make inference on the correlation coefficient of the sample selection model. The author conducts a Monte Carlo study that shows that the Gibbs sampling algorithm performs well regardless of whether the parameters of the model are fully identified or not.¹⁰ On the other hand, Chakravarty and Li (2003) propose a Bayesian algorithm to test the effect of an endogenous binary variable on the profits of a trader (we are not aware of another similar study). They propose a simple Gibbs sampling algorithm that alternates between conditional posterior probability distribution of the parameters. They find no evidence of significant correlation between traders' private information and their profits.

We contribute to the econometric literature on two points. First, we deal with three correlation coefficients because we have three unobservable variables in our model, while Chakravarty and Li (2003) and Van Hasselt (2005) only have to deal with one correlation coefficient. Secondly, both articles reparameterize the elements of the covariance matrix that simplify the sampling procedure and speed up the rate of convergence of the simulated Markov chain. Their algorithms might not be optimal with likelihood functions of irregular shapes. We have included a Metropolis step from the conditional posterior distribution of the covariance matrix that sometimes accepts draws that decrease the likelihood function.¹¹

We analyze endogenous participation in French public timber auctions using a system of three equations. Equation (1) determines the selection process. In other words, it is the probability that there is at least one bid. In case the bidders do not participate in the auction (no bid), the expected payoff of participating, $w_{1,i}$, is zero or negative. Thus, we define $y_{1,i} = 1$ if at least one bidder participates in the auction and $y_{1,i} = 0$ otherwise where i indexes the i^{th} lot.

¹⁰ The Gibbs algorithm is an MCMC algorithm that iteratively draws from the conditional posterior distributions of the parameters and always accepts such draws.

¹¹ See Chen *et al.* (2000).

$$y_{1,i} = \begin{cases} 1 & \text{if } w_{1,i} > 0 \\ 0 & \text{if } w_{1,i} \leq 0 \end{cases} \quad (1)$$

where $w_{1,i} = x_{1,i}' \beta_1 + \varepsilon_{1,i}$, β_1 is of dimension k_1 and $x_{1,i}$ is a set of control variables.

Equation (2) determines the outcome of the endogenous ordinal variable in the selected sample.¹² We define $y_{2,i}$ as an ordinal variable that can take on J values (in the application $J = 3$).

$$y_{2,i} = \begin{cases} 1 & \text{if } w_{2,i} \leq \alpha_1 \\ \dots & \\ j & \text{if } \alpha_{j-1} < w_{2,i} \leq \alpha_j \\ \dots & \\ J & \text{if } w_{2,i} > \alpha_{J-1} \end{cases} \quad \text{if } y_{1,i} = 1 \quad (2)$$

where $w_{2,i} = x_{2,i}' \beta_2 + \varepsilon_{2,i}$, β_2 is of dimension k_2 and $x_{2,i}$ is a set of control variables. We define $\alpha = (\alpha_1, \dots, \alpha_{J-1})'$ as the vector of cutoff parameters to be estimated.

Finally, equation (3) is the hedonic price equation that explains the highest bid $w_{3,i}$ as a function of lot characteristics and the endogenous ordinal participation variable $y_{2,i}$ included as a set of $J-1$ binary variables.¹³ Equation (3) is only observed for lots that have received at least one bid ($y_{1,i} = 1$).

$$w_{3,i} = z_{3,i}' \gamma_3 + z_{2,i}' \delta_2 + \varepsilon_{3,i} = x_{3,i}' \beta_3 + \varepsilon_{3,i} \quad \text{observed for } y_{1,i} = 1 \quad (3)$$

¹² Generally, we only observe the endogenous ordinal variable (2) in the selected sample. For instance, in the application, the ordinal variable is the extent of auction participation, which is only observed for lots that received at least one bid. The observed equation (3) explains the highest bid.

¹³ We decompose the ordinal variable in a set of binary variables so that our results do not depend on the way we have coded the ordinal variable. This is not an issue in equation (2) since the methodology automatically determine the cut-off points regardless of the values of the ordinal variable.

where $z_{2,i} = (z_{2,2,i}, \dots, z_{2,J,i})'$ with $z_{2,j,i} = 1$ if $y_{2,i} = j$ (and $z_{2,j,i} = 0$ otherwise, $j = 2, \dots, J$), δ_2 is a vector of parameters of dimension $J-1$, $x_{3,i} = (z_{3,i}', z_{2,i}')'$ and $\beta_3 = (\gamma_3', \delta_2)'$.

We assume that $\varepsilon_i = (\varepsilon_{1,i}', \varepsilon_{2,i}', \varepsilon_{3,i}')'$ is normally distributed with mean $(0, 0, 0)'$ and covariance Σ for $i = 1, \dots, n$:

$$\Sigma = \begin{bmatrix} 1 & \rho_{12} & \rho_{13}\sigma_3 \\ \rho_{12} & 1 & \rho_{23}\sigma_3 \\ \rho_{13}\sigma_3 & \rho_{23}\sigma_3 & \sigma_3^2 \end{bmatrix}$$

Parameters ρ_{12} , ρ_{13} and ρ_{23} represent the correlations between the unobservable variables. Hence, ρ_{13} is the correlation coefficient of the Heckman sample selection procedure, while ρ_{23} is related to the lack of competition for the lot in the hedonic price equation. Parameter σ_3^2 is the variance of $\varepsilon_{3,i}$. Since probit equations (1) and ordinal probit equation (2) are not identified, we had to impose two restrictions. We chose to normalize the variances of the selection equation and of the endogenous binary variable to 1. These are standard restrictions in probit models.¹⁴

We always observe $(x_{1,i}, y_{1,i})$, but we only observe $y_{2,i}$ and $w_{3,i}$ when $y_{1,i} = 1$.¹⁵ Moreover, the variables $w_{1,i}$ and $w_{2,i}$ are latent. The vector of explanatory variables can be stacked in order to write the (partially) latent model as a Seemingly Unrelated Regressions (SUR) model with an unequal number of observations. Let n_1 be the number of observations for which $y_{1,i} = 0$ and n_2 the number of observations such that $y_{1,i} = 1$, with $n = n_1 + n_2$. We now assume for notational convenience that the data have been sorted according to the values of y_1 . We also note the vector of binary dependent variables as $y = (y_1', y_2)'$. Let $\beta = (\beta_1', \beta_2', \beta_3)'$, $w_1 = (w_{1,1}, \dots, w_{1,n})'$, $w_2 = (w_{2,1}, \dots, w_{2,n_2})'$, $w_3 = (w_{3,1}, \dots, w_{3,n_2})'$ and define $w = (w_1', w_2', w_3)'$. We define ε_1 , ε_2 , ε_3 and ε in a similar fashion.

¹⁴ See Wooldridge (2002) or any other textbook on the econometrics of qualitative dependent variable.

¹⁵ The econometric model identifies all parameters associated with x_1 , x_2 and x_3 because of the non-linearity of the Mill's ratio. However, in most sample selection specifications, some variables are usually not available for the censored observations, which means that the set of variables in x_1 is usually smaller than in x_2 and x_3 .

For notational convenience, we decompose the vectors of unobservable variables according to the selection process: $\varepsilon = (\varepsilon_{11}', \varepsilon_{12}', \varepsilon_2', \varepsilon_3')'$, where the second index equals 1 if $y_{1,i} = 0$ and equals 2 if $y_{1,i} = 1$. Thus the covariance of the unobservable variables is simply

$$\Omega = E\varepsilon\varepsilon' = \begin{bmatrix} \mathbf{I}_{n_1} & 0 \\ 0 & \Sigma \otimes \mathbf{I}_{n_2} \end{bmatrix}$$

where \mathbf{I}_j denotes the identity matrix of dimension $j \times j$. Thus Ω^{-1} is readily obtained. We also decompose and stack the vector of the partially latent dependent variables as $w = (w_{11}', w_{12}', w_2', w_3')'$ and define similarly

$$\mathbf{X} = \begin{bmatrix} x_{11} & 0 & 0 \\ x_{12} & 0 & 0 \\ 0 & x_2 & 0 \\ 0 & 0 & x_3 \end{bmatrix} \quad (n_1+3n_2) \times (k_1+k_2+k_3)$$

The (partially) latent model can be written in matrix format:

$$w = \mathbf{X}\beta + \varepsilon \tag{4}$$

Hence conditional on w and Ω , the estimates of β are simply obtained by a Generalized Least Squares (GLS) regression of (4).¹⁶ Moreover, the matrices $\mathbf{X}'\Omega^{-1}\mathbf{X}$ and $\mathbf{X}'\Omega^{-1}w$ required for the GLS estimates of the parameters of the model are easily computed.

The 4 steps of the Metropolis-Gibbs algorithm are described in appendix 1, and the computation of the partial effects can be found in appendix 2. We have used a flat prior in the Bayesian estimation of the parameters. The model can be extended to include informative prior so as to update implicit prices as the auction process moves on. However, with the large

¹⁶ Since each stage contains different number of observations and generally different sets of explanatory variables, we can not estimate the SUR model with ordinary least squares regression applied to each latent equation separately.

number observations that we have, this procedure is mostly relevant for the first auctions, given that at the end of the auction, the likelihood function will completely dominate the prior distribution in the posterior distribution.¹⁷

5 Results

We estimate the parameters of equations (1), (2) and (3) using the MCMC algorithm. Table 4 gives the Bayesian estimation of the 3-equation model.¹⁸ All the variables available have been used to build the model but only significant variables have been kept in each equation. The signs of the estimated coefficients are coherent and intuitive, except for the variable ‘no restriction’ for which the coefficient is surprisingly negative in equation (3).

Remember equation (1) gives the probability that a lot will receive at least one bid. Equation (2) gives the intensity of competition (*i.e.* the number of bidders) for a lot: (*i*) probability that there is no competition, *i.e.* only 1 bid, (*ii*) probability that there are 2 bids, and (*iii*) probability that there are 3 or more bids. Equation (3) gives the estimated value of the log of the highest bid.

¹⁷ To conclude this methodological section, one could wonder if we need three equations. Our model could have been written within an ordered probit framework if one only uses one latent variable for the number of bidders (lots without bids are interpreted as censored observations). However this specification is not as flexible, because it implies that the unobservable variable that determine whether a lot receives at least one bid is perfectly correlated with the unobservable variable that determine the number of bidders conditional on a lot receiving at least one bid. There are indeed good reasons to believe that these unobservable variables are not perfectly correlated.

¹⁸ Convergence of the MCMC algorithm was reached quickly. We removed the first 100000 iterations and kept the next 1000000 iterations for inference.

We also have estimated the probit equation (1) and the ordinal probit equation (2) separately and ran a Heckit procedure using sample selection equation (1) and hedonic bid equation (3) as benchmarks. Results were similar to the Bayesian estimation¹⁹. This is expected since the coefficient associated with the inverse Mills ratio is not significantly different from zero. However, this result is not reliable with the Heckit procedure and depends on the variables used to build the model. Actually, if we use only variables that are available in the sale catalogue, we may observe a selection bias while the Bayesian procedure does not detect any problem of sample selection bias.²⁰ Therefore estimations of the correlation coefficients ρ_{13} using the Heckit procedure can lead to misleading inference.

Controlling for endogenous participation and for the characteristics of the lots, we find that, compared to the highest bid for lots with two bids, on average: (i) lots with only one bid

¹⁹ Results of these preliminary estimations are available upon request.

²⁰ Such a model is available upon request.

receive a highest bid that is 22.31% below and (ii) lots with three or more bids receive a highest bid that is 37.09% higher. These results on the cost of low competition are very significant and imply that it is important for the seller to have enough bidders for each timber lot. This objective must be kept in mind when she determines the number of lots to put on the market, their size and their composition. In addition, it would be wise to consider any improvement in the sale format that would lower the participation cost for any potential buyer. For example, a better description of the lots (eventually by a third party and with pictures on Internet for example) could encourage some potential buyers to bid on lots that they did not visit.

Two other results deserve special mention. First, the degree of intra-lot heterogeneity is a significant variable in all 3 equations: the Herfindahl index has a significant positive effect. Thus, during an auction with at least one bidder, competition increases for lots that are more homogenous in species, *i.e.* with an Herfindahl index closer to one. In addition, a higher Herfindahl index increases the highest bid. Thus, concentrated lots with a Herfindahl index close to 1 (in other words lots that are not heterogeneous) have a sale premium. Boltz, Carter and Jacobson (2002) highlight the importance of intra-lot heterogeneity on auction prices of mixed species lots from timber auctions in North Carolina. Their Tobit estimation results (the reserve price being announced) show that increased heterogeneity leads to lower sale prices. In some way, they interpret such decrease in the revenue as an opportunity cost for ecosystem management where biodiversity is a desired constraint. Here, the opportunity cost of maintaining mixed forest can be estimated from the partial effect associated to the Herfindahl index: increasing the index by 1% increases the expected highest bid by 0.9164%. This figure can be found in Table 5 below which gives the partial effect for every variable used in this model. The partial effect of a variable corresponds here to the total impact of that variable on the expected log of the highest bid taking into account the possible selection bias of non submitted lots and the impact of that variable on the number of bidders.

Second, the coefficient associated with the ‘relative position of a lot’ in the sale is significantly positive in equation (2) and (3). This indicates that lots put on the market at the end of a sale have a higher probability to receive more bids and to obtain a better highest bid than lots auctioned in the beginning of the sale, after we control for quality differences. This last result implies that the decline in prices often observed in sequential auctions is not present in our sample of timber auctions. On the contrary, prices tend to increase for

hardwood lots during a sale. This could be due to cautious behavior of the bidders in the beginning of the auctions and more aggressive bids at the end of the auctions. This interpretation is confirmed by two additional results. First, the probability that a lot receives at least one bid is significantly lower in the first sale of the campaign. The variable ‘first sale’ has a significant negative impact in equation (1) and (2): bidders wait and see. Second, the variable ‘last sale’ has a significant positive impact in the hedonic price equation (3). This result reinforces the ‘relative position of a lot’ variable on a larger scale. Indeed, the highest bid increases during a sale (which is composed of many timber lots put on sale the same day), moreover the highest bids tend to be higher in the tenth sale (the one that took place the last day of the timber sale campaign).

6 Conclusion

Using detailed data set on timber auctions in Lorraine, we have highlighted the importance of endogenous participation on auction results, focusing on lots that do not receive any bids and on the degree of competition when lots receive at least one bid. We have proposed a methodology to deal with both issues at the same time. The econometric method can easily be extended to deal with truncated or censored dependant variables in the hedonic price equation, when the reserve price is announced.

Our results can help public forest services to determine a relevant reserve price for each lot according to its characteristics. In order to avoid auctions with one bid or less, the methodology could also be used to propose more attractive lots and to better understand demand factors. Our hedonic price function for stumpage value gives interesting information about the implicit price of each lot characteristic for the optimal lot composition. We have discussed the impact of the relative order of the lot in the sale and the impact of the intra lot heterogeneity, but our results show that many variables have a significant impact on the participation process and on the auctioned price including the type of cutting, the type of stand, the harvesting conditions, the volume and the composition of the lot. These results can help the forest public services to manage forest more efficiently so as to offer more attractive lots. Besides, our results highlight on the high cost of the low participation in French timber auctions and lead us to recommend any measure that would increase the number of bidders. In particular, it would be wise to implement any idea that would lower participating cost.

Finally, our methodology can also be useful for bidders to define a bid that increases their probability of winning at a lower cost. Models can be elaborated according to which variables are available to the agent just before the auction.

Appendix 1: The Metropolis-Gibbs sampling algorithm

The Metropolis-Gibbs sampling algorithm proceeds in 4 steps. The first step is a standard data augmentation step. We use a uniform prior for β , α , ρ_{12} , ρ_{13} , ρ_{23} and a non-informative prior for σ_3 : $p(\beta, \alpha, \rho_{12}, \rho_{13}, \rho_{23}, \sigma_3) \propto 1/\sigma_3$.²¹ To simplify notations we have dropped the dependence of Ω on Σ and the dependence of Σ on $(\rho_{12}, \rho_{13}, \rho_{23}, \sigma_3)'$ when there is no ambiguity.

Step 1. $w_1, w_2 \mid \alpha, \beta, \Sigma, w_3, y, X$

In the first step, we only need to draw w_1 and w_2 since w_3 is observed. When $y_{1,i} = 0$, we know that $w_{1,i} < 0$, hence for those observations ($i = 1, \dots, n_1$), we draw $w_{1,i}$ from the standard truncated normal distribution with mean $x_{1,i}'\beta_1$ and variance 1 truncated on $(-\infty, 0)$. We use the optimal algorithm of Robert (1995) to draw from the truncated normal distribution.²² For the other observations ($i = n_1+1, \dots, n$), we know that conditionally on $\alpha, \beta, \Sigma, y, X, (w_{1,i}, w_{2,i}, w_{3,i})'$ has a joint normal distribution with mean $(x_{1,i}'\beta_1, x_{2,i}'\beta_2, x_{3,i}'\beta_3)'$ and covariance Σ . Thus,

$$w_{1,i} \mid w_{2,i}, \alpha, \beta, \Sigma, y, w_3, X \sim TN(\mu_{1|23}, \Sigma_{1|23}; B_1)$$

where $TN(a, b; c)$ denotes the normal distribution with mean a , variance b truncated in subspace c and $B_1 = \{z_1 \in \mathbf{R}: z_1 > 0\}$. The conditional moments $\mu_{1|23}$ and $\Sigma_{1|23}$ are given by the standard formulas of the conditional distribution from a multivariate normal distribution. Similarly,

$$w_{2,i} \mid w_{1,i}, \alpha, \beta, \Sigma, y, w_3, X \sim TN(\mu_{2|13}, \Sigma_{2|13}; B_2)$$

²¹ The choice of the prior distribution does not matter much when there is a large number of observations, which is usually the case for auction data. Moreover, using the uniform prior distribution provides a direct mean of comparison with the maximum likelihood procedures.

²² Using the inverse c.d.f. method yielded unreliable results.

where $B_{2j} = \{z \in \mathbf{R}: a_{j-1} < z \leq a_j\}$ if $y_{2,i} = j$ (by convention, $\alpha_0 = -\infty$ and $\alpha_J = +\infty$).

Step 2. $\alpha \mid \beta, \Sigma, \mathbf{y}, \mathbf{w}, \mathbf{X}$

It is easy to see that the conditional posterior distribution of α_j is (for $j = 1, \dots, J-1$):

$$\alpha_j \mid \beta, \Sigma, \mathbf{y}, \mathbf{w}, \mathbf{X} \sim U(\text{Max}\{w_{2,i}: y_{2,i} = j\}, \text{Min}\{w_{2,i}: y_{2,i} = j+1\})$$

Step 3. $\beta \mid \alpha, \Sigma, \mathbf{y}, \mathbf{w}, \mathbf{X}$

As discussed in the presentation of the (partially) latent model, the conditional distribution of β is readily seen to be:

$$\beta \mid \alpha, \Sigma, \mathbf{y}, \mathbf{w}, \mathbf{X} \sim N((\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \mathbf{X}'\Omega^{-1}\mathbf{w}, (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}).$$

Step 4. $\Sigma \mid \alpha, \beta, \mathbf{y}, \mathbf{w}, \mathbf{X}$

The conditional posterior distribution of Σ is not standard,

$$\Sigma \mid \alpha, \beta, \mathbf{y}, \mathbf{w}, \mathbf{X} \propto |\Sigma|^{-n/2} \exp(-\varepsilon'\Omega^{-1}\varepsilon/2) / \sigma_3,$$

but can be simulated using Metropolis step. Define $\sigma = (\rho_{12}, \rho_{13}, \rho_{23}, \sigma_3)'$. We use a normal jumping distribution $N(\sigma, \theta' \mathbf{I}_{4 \times 4})$.²³

²³ We set the elements of θ in the Metropolis-Hastings algorithm to obtain an acceptance rate between 0.2 and 0.25. In general a large step size decreases the speed of convergence of the algorithm but enables to get out of problematic areas of the likelihood function more quickly, while a small value would make the algorithm converge faster at the cost of getting stuck in undesirable areas. The range of values that we have used is standard for the number of parameters used in the application and was found to be a good compromise between the two effects mentioned above. Note that this range of acceptance rates has been shown to be optimal for MCMC algorithms that use a normal jumping distribution. For other sampling schemes, the optimal acceptance rate has to be computed and could be different from the above values. Draws that resulted in values of the correlation coefficients below -1 or above 1, as well as draws not resulting in a positive covariance matrix were rejected. Note also that we used a log transformation of the various probabilities in order to avoid numerical underflows.

Appendix 2: Computation of the partial effects

Let X denotes the matrix of explanatory variables defined in the text. The observed highest bid equation is

$$w_3 = \delta_{21} z_{22} + \delta_{22} z_{23} + z_3' \gamma_3 + \varepsilon_3 \quad (\text{A1})$$

The expected bid conditional on participation is

$$E(w_3 | X, y_1=1) = \delta_{21} E(z_{22} | X, y_1=1) + \delta_{22} E(z_{23} | X, y_1=1) + z_3' \gamma_3 + \gamma_1 \lambda(x_1' \beta_1) \quad (\text{A2})$$

Where is $\lambda(\cdot)$ is the inverse mill ratio and $\gamma_1 = \rho_{13}/\sigma_3$. The partial effects of the last two terms of (A2) are given from standard computations in the Heckman model. It remains to find the partial effect with respect to the first two terms of the right-hand side of (A2). We can write (dropping the conditioning on X to simplify notations):

$$E(z_{22} | y_1=1) = p(y_2 = 2 | y_1=1) = p(\alpha_1 - x_2' \beta_2 < \varepsilon_2 < \alpha_2 - x_2' \beta_2 | \varepsilon_1 > -x_1' \beta_1) = P_1 \quad (\text{A3})$$

$$E(z_{23} | y_1=1) = p(y_2 = 3 | y_1=1) = p(\varepsilon_2 > \alpha_2 - x_2' \beta_2 | \varepsilon_1 > -x_1' \beta_1) = P_2$$

We decompose the conditional probability as follows:

$$P_1 = \int_D p(\alpha_1 - x_2' \beta_2 < \varepsilon_2 < \alpha_2 - x_2' \beta_2 | \varepsilon_1) p(\varepsilon_1 | \varepsilon_1 > -x_1' \beta_1) d\varepsilon_1,$$

where $D = [-x_1' \beta_1; +\infty]$ is the domain of integration with respect to ε_1 . Using the fact that ε_1 is normally distributed, we can write where $f(\cdot)$ is the standard normal density.

$$P_1 = \int_D p(\alpha_1 - x_2' \beta_2 < \varepsilon_2 < \alpha_2 - x_2' \beta_2 | \varepsilon_1) \phi(\varepsilon_1) / (1 - \Phi(-x_1' \beta_1)) d\varepsilon_1 \quad (\text{A4})$$

Using a property of the conditional distribution of a normally distributed random variable, $p(\alpha_1 - x_2' \beta_2 < \varepsilon_2 < \alpha_2 - x_2' \beta_2 | \varepsilon_1) = \int_E p(\varepsilon_2 | \varepsilon_1) d\varepsilon_2 = \int_E \phi(1 - \rho_{12} \varepsilon_1; 1 - \rho_{12}^2) d\varepsilon_2$, where $E = [\alpha_1 - x_2' \beta_2; \alpha_2 - x_2' \beta_2]$ and $\phi(a; b)$ denotes the density of a normally distributed variable with mean a and variance b . We use properties of the normal distribution to write

$$\begin{aligned}
p(\alpha_1 - x_2' \beta_2 < \varepsilon_2 < \alpha_2 - x_2' \beta_2 \mid \varepsilon_1) &= \int_{E'} \phi(\varepsilon_2) \, d\varepsilon_2 \\
&= \Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}) - \Phi((\alpha_1 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}), \quad (A5)
\end{aligned}$$

where $E' = [(\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}; (\alpha_1 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}]$.

Substituting (A5) in (A4), we have

$$\begin{aligned}
P_1 = \int_D [&\Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}) - \Phi((\alpha_1 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)})] \\
&\phi(\varepsilon_1) / (1 - \Phi(-x_1' \beta_1)) \, d\varepsilon_1
\end{aligned}$$

Similarly,

$$P_2 = \int_D [1 - \Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)})] \phi(\varepsilon_1) / (1 - \Phi(-x_1' \beta_1)) \, d\varepsilon_1$$

We now compute the partial effect of P_1 with respect to x_k (the implicit price of the characteristic) that belongs to the set of variables x_1 and x_2 :

$$\begin{aligned}
\partial P_1 / \partial x_k &= [1 - \Phi(-x_1' \beta_1)]^{-1} \{ \phi(-x_1' \beta_1) (-\beta_{1k}) / (1 - \Phi(-x_1' \beta_1)) \times \\
&\int_D [\Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}) - \Phi((\alpha_1 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)})] \phi(\varepsilon_1) \, d\varepsilon_1 \\
&+ [\Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} x_1' \beta_1)) / \sqrt{(1 - \rho_{12}^2)}) - \Phi((\alpha_1 - x_2' \beta_2 - (1 - \rho_{12} x_1' \beta_1)) / \sqrt{(1 - \rho_{12}^2)})] \times \\
&\quad \phi(-x_1' \beta_1) \beta_{1k} \\
&- \int_D [\phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)}) - \phi((\alpha_1 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)})] \times \\
&\quad (\beta_{2k} / \sqrt{(1 - \rho_{12}^2)}) \phi(\varepsilon_1) \, d\varepsilon_1 \}
\end{aligned}$$

Integrals in the previous formula can be computed by simulation using the GHK algorithm for instance. Similarly,

$$\begin{aligned}
\partial P_2 / \partial x_k &= [1 - \Phi(-x_1' \beta_1)]^{-1} \{ \phi(-x_1' \beta_1) (-\beta_{1k}) / (1 - \Phi(-x_1' \beta_1)) \times \\
&\int_D [1 - \Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)})] \phi(\varepsilon_1) \, d\varepsilon_1 \\
&+ [1 - \Phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} x_1' \beta_1)) / \sqrt{(1 - \rho_{12}^2)})] \phi(-x_1' \beta_1) \beta_{1k} \\
&+ \int_D [\phi((\alpha_2 - x_2' \beta_2 - (1 - \rho_{12} \varepsilon_1)) / \sqrt{(1 - \rho_{12}^2)})] (\beta_{2k} / \sqrt{(1 - \rho_{12}^2)}) \phi(\varepsilon_1) \, d\varepsilon_1 \}
\end{aligned}$$
