## Abstract

Nitrogen is an essential macronutrient and its availability in soil plays a critical role in plant growth, development and impacts agricultural productivity. Plants have evolved different strategies to sense and respond to heterogeneous nitrogen distribution. Modulating root system architecture, including primary root growth and branching, is among the most essential plant adaptations to ensure adequate nitrogen acquisition. However, the immediate molecular pathways coordinating the adjustment of root growth in response to varying nitrogen sources are poorly understood. Here, using a combination of physiological, live *in vivo* high- and super resolution imaging, we describe a novel adaptation strategy of root growth on available nitrogen source. We show that growth, *i.e.* tissue-specific cell division and elongation rates are fine-tuned by modulating auxin flux within and between tissues. Changes in auxin redistribution are achieved by nitrogen source dependent post-translational modification of PIN2, a major auxin efflux carrier, at an uncharacterized, evolutionary conserved phosphosite. Further, we generate a computer model based on our results which successfully recapitulate our experimental observations and creates new predictions that could broaden our understanding of root growth mechanisms in the dynamic environment.

## Introduction

The ability to sense and adapt to fluctuations in nutrient availability is essential for the survival of all organisms. Every life form on our planet possesses delicate mechanisms for sensing and reacting to the variable nutrient status and adjusts their behavior to maintain growth or cope with stress caused by malnutrition. Mineral nutrients absorbed from the soil are major determinants of plant growth and development. Although required, fluctuations in their availabilities either to sub- or supra-optimal levels often have detrimental effects on plant metabolism and physiology, thereby attenuating plant fitness. Hence, the acquisition of mineral nutrients from the soil needs to be tightly controlled and endogenous levels within a plant body maintained at a physiological optimum level. At the molecular level, balancing nutrient acquisition with the plant's requirements implies that there is close communication between pathways controlling uptake, distribution and homeostasis of nutrients and the pathways coordinating plant growth and development.

The root system perceives and integrates local and systemic signals on the nutrient status to regulate activity of pathways mediating nutrient uptake and distribution. An important

component of the plant's nutrient management strategy involves a rapid modulation of the root growth and development. In response to nutrient availability, root meristem activity and elongation growth of primary root, as well as root branching, are adjusted in order to optimize nutrient provision to the plant body<sup>1</sup>. Production of new cells is essential for sustainable root growth; however, enhancement of the cell division machinery typically occurs within a range of hours<sup>2</sup>. In contrast, rapid modulation of cell elongation and manifold increase in cell volume would ensure faster growth responses<sup>3</sup>. Hence, in fluctuating environmental conditions root growth kinetics relies on the coordination of rapid elongation growth and adjustment of proliferation activity of the meristem.

Nitrogen (N) is a key macronutrient present in many key biological molecules and therefore constitutes a limiting factor in agricultural systems<sup>4</sup>. Although plants are dependent on an exogenous N supply and use nitrate ( $\text{NO}_3^-$ ), nitrite ( $\text{NO}_2^-$ ), and ammonium ( $\text{NH}_4^+$ ) as major sources of inorganic N, their preference for different inorganic forms depends on plant adaptation to soil<sup>4,5</sup>. For example; wheat, maize, canola, beans, sugar beet, *Arabidopsis* and tobacco grow preferentially on  $\text{NO}_3^-$  nutrition, whereas, rice and pine grow on  $\text{NH}_4^+$  nutrition. Fluctuations in both concentrations and the form of nitrogen sources available in the soil have prominent effects on root system growth and development<sup>6,7</sup>. Deficiency in nitrogen severely interferes with root elongation growth and development; low to medium availability of nitrogen enhances root growth and branching to promote the exploitation of this macronutrient, whereas high levels of availability might inhibit the elongation growth of primary and lateral roots<sup>8</sup>. When exposed to local nitrate-rich zones, the root system responds by enhancing lateral root (LR) outgrowth<sup>9-11</sup>. In the model plant *Arabidopsis thaliana*, the local availability of  $\text{NO}_3^-$  and  $\text{NH}_4^+$  seems to have complementary effects on the LR development ( $\text{NH}_4^+$  stimulates branching, whereas  $\text{NO}_3^-$  induces LR elongation<sup>11,12</sup>). These complex adaptive responses of the root organ to N sources and heterogeneity in availability are regulated by a combination of systemic and local signaling<sup>13</sup>. The impact of available sources of N on the root system is closely interconnected with the activity of plant hormones including auxin, cytokinin, ABA, ethylene and others<sup>14-16</sup>. In recent years, a number of studies have demonstrated that auxin biosynthesis, transport, and accumulation is altered in response to different N regimes in maize<sup>17,18</sup>, soybean<sup>19</sup>, pineapple<sup>20</sup> and *Arabidopsis thaliana*<sup>16,21-23</sup>. In *Arabidopsis*, several key auxin-related regulatory modules that respond to nitrogen availability were identified including *TAR2*, a gene involved in auxin biosynthesis, transporters of auxin such as *PIN-FORMED 1* (*PIN1*), *PIN2*, *PIN4* and *PIN7* and molecular components, which control their subcellular trafficking<sup>21,24</sup>. At the level of auxin signaling, Auxin Response Factor *AUXIN RESPONSE*

*FACTOR 8* (*ARF8*, encoding a transcription factor of the auxin signaling machinery) was identified as a N responsive gene in the pericycle<sup>25</sup>. *ARF8* together with its associated microRNA167s is involved in the control of the ratio between LR initiation and emergence<sup>25–28</sup>. Another mechanism of nitrogen – auxin interplay underlying adaptation of the root system is mediated through NRT1.1, nitrate transceptor<sup>29</sup>. Its dual auxin-nitrate transport activity has been shown to play an important role in the adaptation of the root system, in particular, LR emergence to nitrate availability<sup>21,30</sup>.

Flexible modulation of primary root growth to fluctuations in nitrogen resources has been recognized as a prominent foraging strategy to optimize N exploitation<sup>31</sup>. However, the mechanisms that control the rapid reconfiguration of root growth dynamics in response to diverse N sources are still poorly understood. Here, to dissect the tissue and cellular mechanisms underlying the early phases of this adaptive process we focused on the primary responses of *Arabidopsis* roots to alterations in the available source of N such as  $\text{NH}_4^+$  and  $\text{NO}_3^-$ . We performed real time vertical confocal imaging to capture the earliest root responses after the replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$ . We found that in roots supplied with  $\text{NH}_4^+$ , local attenuation of meristematic activity in the epidermis results in the earlier transition of epidermal cells into elongation when compared to the cortex, thus generating asynchronous elongation of the adjacent tissues. Substitution of  $\text{NH}_4^+$  for  $\text{NO}_3^-$  led to a rapid enhancement of root growth associated with the simultaneous entrance of more cells at the root transition zone into elongation, and the subsequent re-establishment of a critical balance between cell proliferation and elongation. We demonstrate that root epidermis and cortex tissues supplemented with  $\text{NO}_3^-$  synchronize their growth patterns. We show that the essential mechanism underlying this flexible adaptation of root growth involves nitrate-dependent fine-tuning of the auxin transport mediated by PIN2. In roots supplied with different forms of N, distinct localization patterns of PIN2 are generated as a result of dynamic PIN2 subcellular trafficking. Intriguingly, phosphoproteome analysis of PIN2 (Vega et al.) led to the identification of an uncharacterized nitrate-sensitive phosphorylation site. The functional characterization of PIN2 and its phosphor-variants suggest that the N source dependent modulation of PIN2 phosphorylation status has a direct impact on the flexible adjustment of PIN2 localization pattern, and thereby facilitates the adaptation of root growth to varying forms of N supply. Finally, we integrated experimental data regarding the nitrogen-dependent root growth into a quantitative computer model. Our computer model recapitulated *in planta* patterning from a minimal set of assumptions and made predictions that were tested experimentally. Taken together, we present a quantitative mechanistic model of how *Arabidopsis* primary root growth is fine-tuned to

different N sources. We hypothesize, that the flexible modulation of growth patterns relying on nutrient response on auxin transport is an important part of the intelligent strategy, to enable plant root adaption to the dynamically changing environment and thus maintain its sustainable growth.

## Results

### *Root growth rapidly adjusts to form of nitrogen source*

To explore how primary root responds and adapts to different forms of N, *Arabidopsis* seedlings were grown on  $\text{NH}_4^+$  as an exclusive N source for five days (5 DAG) and afterward transferred on media containing either  $\text{NH}_4^+$  or  $\text{NO}_3^-$ . We found that replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$  rapidly enhanced root length and already 6 hours after transfer (HAT), roots were significantly longer compared to these supplied with  $\text{NH}_4^+$  (Fig. S1a). In general, root growth is determined by the elongation of cells, which are constantly produced by the root apical meristem. To study processes that underlie the adaptation of root growth to different forms of N a vertical confocal microscope equipped with a root tracker system was employed. Using this setup, we were able to detect and monitor the earliest root responses with a high cellular resolution<sup>32</sup>. To minimize the interference of physiological conditions for seedling development, a light-dark regime was maintained in course of the root tracking. After the transfer of wild type (Col-0) seedlings to  $\text{NH}_4^+$  containing medium root growth rate (RGR) was enhanced, presumably as a response to stress caused by transfer of seedlings to a fresh plate. Within ~120 min RGR stabilized at an average speed of  $1.37 \pm 0.025 \mu\text{mmin}^{-1}$ . Transition to dark period correlated with a rapid drop of RGR to  $0.98 \pm 0.029 \mu\text{mmin}^{-1}$ , which was maintained during the dark phase and at the light recovered again to  $1.27 \pm 0.048 \mu\text{mmin}^{-1}$ . Seedlings transferred to  $\text{NO}_3^-$  reacted by an increase of RGR to  $1.77 \pm 0.042 \mu\text{mmin}^{-1}$  and similarly to roots on  $\text{NH}_4^+$ , during the dark period their RGR decelerated and was retrieved to  $1.81 \pm 0.051 \mu\text{mmin}^{-1}$  at the light (Fig. 1a, Supplemental video 1). Hence, provision of  $\text{NO}_3^-$  caused a rapid enhancement of RGR when compared to  $\text{NH}_4^+$ , but it did not interfere with its circadian rhythmicity<sup>33</sup>.

To gain more insight into the mechanistic basis underlying the rapid increase of root length after substitution of  $\text{NH}_4^+$  for  $\text{NO}_3^-$ , we focused on cells in the transition zone (TZ). The TZ is located between the root apical meristem and elongation zone, and cells while passing this developmental zone undergo essential modifications associated with their transition from the proliferative to the elongation phase<sup>34,35</sup> (Fig. 1b). Time-lapse experiments capturing root

growth from 2 to 3.76 hours after transfer combined with a tracking of cell membranes pointed at differences in the elongation pattern of epidermal cells in roots supplied with either  $\text{NH}_4^+$  or  $\text{NO}_3^-$ . While, in roots supplemented with  $\text{NH}_4^+$  only a few epidermal cells enter into elongation phase. Provision of  $\text{NO}_3^-$  increased number of elongating cells in the TZ (Fig. 1b, Supplemental video 2). Next, we analyzed in detail 18 roots 12 HAT on either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  and measured length of the epidermal cells across the meristematic, transition and the start of the elongation zones. The analyses suggested that on  $\text{NO}_3^-$  more epidermal cells enter into transition phase, as indicated by an increased number of cells 30-40  $\mu\text{m}$  long when compared to roots on  $\text{NH}_4^+$  (Fig. S1b). Despite the stimulating impact of  $\text{NO}_3^-$  on cell transition into the elongation phase, no differences in the maximal length of fully differentiated epidermal cells between roots on  $\text{NO}_3^-$  and  $\text{NH}_4^+$  were detected (Fig. S1c). This suggests that  $\text{NO}_3^-$  promoted root growth is a result of modulated elongation kinetics of cells along the longitudinal root growth axis and not increase of the maximal cell length.

To sustain root growth, the rate of cell elongation and differentiation has to be tightly balanced with the production of new cells in the root meristem<sup>36</sup>. Hence, enhanced growth of cells after replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$  could lead to depletion of the meristem if expansion of cells would prevail over a new cell production. To examine how root meristem adapt to change in N supply, cell length and frequency of divisions in epidermis and cortex along the longitudinal root growth axis were closely inspected 12 HAT. Surprisingly, length of epidermal cells started to increase from the 11<sup>th</sup> cell on (cell number was counted from quiescent center (QC)) in roots supplied with  $\text{NH}_4^+$  (Fig. 1c and Supplemental Document 1a-b). In contrast, roots on  $\text{NO}_3^-$  exhibited an increase in size from the 13<sup>th</sup> epidermal cells (Fig. 1d, S1d Supplemental Document 1a-b). Unlike the epidermis, the length profiles of cortex cells were not significantly different between roots supplied with either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  (Fig. S1e, Supplemental Document 1a-b). Therefore, the growth of epidermal and cortex cells in roots on  $\text{NH}_4^+$  displayed clearly asynchronous behavior (Fig. 1c, d). Additionally, a machine learning approach was applied to regression analysis for assessing the importance of each variable (i.e. treatments: ammonium and nitrate, tissues: epidermis and cortex, cell positions) on cell length differences. Analysis of deviance was followed by estimated marginal mean (emmean) comparisons of cell lengths in different tissues (epidermis vs cortex) at each cell position (1-20 from QC) for each treatment (ammonium vs nitrate). The results show that ammonium and nitrate treatments affect the cell positions differentially: epidermal cells from the 17<sup>th</sup> up to the 20<sup>th</sup> position are significantly longer on ammonium while cell length in cortex is not affected

by the treatments. (Supplemental Document 1a-b). Results were confirmed by recursive partitioning analysis and shown in a decision tree (Supplemental Document 1c).

The distinct elongation pattern of epidermal and cortex cells detected in roots on  $\text{NH}_4^+$  can only be sustained if cell divisions in cortex compensate for an earlier start of cell elongation in the epidermis. Accordingly, the scoring of cell division events (visualized by DAPI) revealed a higher number of mitotic events in cortex compared to epidermal cells in roots transferred to  $\text{NH}_4^+$ . On  $\text{NO}_3^-$  similar frequency of cell divisions in both epidermal and cortex cell files was observed (Fig. 1e, Fig. S2a). Finally, monitoring of the cell cycle reporter *CyclinB::GUS* expression 2 days after transfer (DAT) to either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  revealed enhanced reporter expression and overall enlargement of the meristematic zone in roots supplemented with  $\text{NO}_3^-$  (Fig. S2b).

Altogether, these data indicate that roots adopt distinct growth strategies involving fine-tuning of cell division and expansion across adjacent tissues to adapt to different forms of N. In roots supplied with  $\text{NH}_4^+$ , the meristematic activity of epidermal cells is attenuated, which results in their earlier transition into the elongation phase when compared to the cortex. Provision of  $\text{NO}_3^-$  increases the number of epidermal cells in the TZ (Fig. 1b, S1b), which is one of the earliest detectable adaptive responses. Subsequently, within twelve hours, the frequency of cell division in the epidermis increases, which results in shift of balance between cell division and elongation and more synchronized growth of cortex and epidermis. Eventually, a long-term supply of  $\text{NO}_3^-$  enables enlargement of the root apical meristem compared to roots supplied with  $\text{NH}_4^+$ .

### ***Level and pattern of auxin activity in roots are modulated by form of nitrogen source***

The plant hormone auxin is an essential endogenous regulatory cue that determines key aspects of root growth. Interference with auxin biosynthesis<sup>37</sup>, signaling<sup>38</sup> or distribution<sup>39</sup> at the root tip has a significant impact on the meristem maintenance, and transition of meristematic cells into elongation and differentiation phase. Distinct growth patterns observed in roots supplemented with different forms of N prompted us to monitor distribution of auxin at the root tip. Quantification of the LUCIFERASE activity in protein extracts from roots carrying the auxin sensitive *DR5::LUCIFERASE* reporter revealed that already one hour after transfer to  $\text{NO}_3^-$  containing medium auxin response increases when compared to roots transferred to  $\text{NH}_4^+$  supplemented medium (Fig. S3a). To closely inspect the auxin distribution in a cell lineage-specific manner a ratiometric degradation based *R2D2* auxin reporter was implemented<sup>40</sup>. In accordance with observations based on the *DR5::LUCIFERASE* reporter, a

decreased ratio between DII-Venus (green) and mDII-Tomato (red) fluorescent signals indicated increased levels of auxin activity in the central cylinder of roots in response to replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$  (Fig. S3b).

In addition, we focused on the detailed profiling of the R2D2 reporter in the epidermis and the cortex (Fig. S3c). Interestingly, we detected an overall increase of auxin activity in epidermal cells when compared to cortex cells in roots supplied with  $\text{NH}_4^+$ , whereas no difference between these two cell files were detected in roots on  $\text{NO}_3^-$  (Fig. 2a, b). Furthermore, on  $\text{NH}_4^+$  there was an increase of auxin activity in epidermal cells when compared to cortex cells (starting from ~ 11<sup>th</sup> cell from the QC), while in roots supplied with  $\text{NO}_3^-$  the auxin activity profiles followed similar trends of steady increase in both cortex and epidermal cell files (Fig. 2a, b). Altogether, these analyses indicate that pattern of auxin activity at root meristems might adapt to specific N conditions. In roots supplied with  $\text{NH}_4^+$ , the early steep gradient of auxin signaling in epidermal cells correlates with their early transition into the rapid elongation phase. Whereas in cortex cells, auxin reaches concentrations which might drive elongation in more proximal cells. Substitution of  $\text{NH}_4^+$  by  $\text{NO}_3^-$  attenuates differences in profiles of the auxin distribution between the cortex and the epidermal cell files, which would lead to the synchronized cell growth (Fig. 2a, b compared to Fig. 1c, d).

### ***Nitrogen source affects basipetal auxin transport***

Directional cell-to-cell transport of auxin significantly contributes to the establishment of the auxin activity pattern at the root tip. The Polar auxin transport (PAT) machinery, composed of AUX/LAX influx and PIN efflux carriers, directs the flow of auxin from the shoot acropetally through the stele towards the root tip; from where it is via epidermis basipetally redistributed to the elongation zone. At the TZ, auxin might be redirected from the basipetal stream across the cortex, endodermis and pericycle back to stele and root tip, thereby fine-tuning levels of auxin at the TZ<sup>41,42</sup>. The modulation of auxin activity pattern in the outer tissues detected after the replacement of  $\text{NH}_4^+$  for  $\text{NO}_3^-$  suggests that there are alterations of the basipetal auxin transport. To explore how different forms of N affect the flow of auxin in basipetal direction, transport assays using radioactively labeled auxin (<sup>3</sup>H-IAA) were performed. Six hours after applying <sup>3</sup>H-IAA to the root tip, radioactivity in the proximal zone of the primary roots supplied with  $\text{NH}_4^+$  was significantly lower when compared to roots on either  $\text{NO}_3^-$  supplemented or standard Murashige and Skoog (MS) medium (Fig. 3A). These results indicate that basipetal auxin transport can be modulated by available source of N, and provision of  $\text{NO}_3^-$  enhances flux of auxin in shootward direction when compared to  $\text{NH}_4^+$ .

The PIN2 auxin efflux carrier is amongst the principal components of PAT mediating basipetal transport of auxin in roots<sup>43,44</sup>. To test whether adjustment of the basipetal auxin flow in response to different sources of nitrogen is dependent on activity of PIN2, we tested *eir1-4*, a mutant defective in this efflux transporter. In agreement with previous reports<sup>45</sup>, a significantly lower radioactivity in the proximal root zone of the *eir1-4* was detected when compared to wild type roots on MS medium (Fig. 3a). Noteworthy, no radioactivity increase in the proximal zone of *eir1-4* roots was observed in roots supplied with NO<sub>3</sub><sup>-</sup> when compared to NH<sub>4</sub><sup>+</sup> (Fig. 3a), pointing towards PIN2 function in the flexible adjustment of the basipetal auxin flow in response to form of N source. To further examine the role of the PIN2 mediated transport in establishment of distinct auxin patterns at root tips supplemented with different forms of N, we monitored the auxin sensitive reporter DII-Venus and its stabilized auxin responsive analog mDII-Venus<sup>46</sup> as a reference in *eir1-4* and Col-0 roots. The expression pattern of DII-Venus reporter in Col-0 roots was largely consistent with what we observed using the R2D2 reporter (Fig. S4a-b). In Col-0 roots supplied with NH<sub>4</sub><sup>+</sup>, a reduced DII-Venus signal indicated a higher auxin activity in epidermal cells when compared to the cortex. Also, consistently with the R2D2 reporter, a steeper slope of auxin activity in epidermis when compared to cortex (with onset at ~8<sup>th</sup> cell distance from QC) was detected in roots supplied with NH<sub>4</sub><sup>+</sup>, whereas in roots on NO<sub>3</sub><sup>-</sup>, auxin activity both in epidermis and cortex followed similar trends (Fig. 3b, c compared to Fig. 2a, b and Fig. S4a, b). *eir1-4* was severely affected in adjustment of auxin pattern to different N sources. When compared to Col-0, overall higher levels of auxin activity in both epidermal and cortex cells and a shallower slope of auxin activity increase in the epidermis was observed in *eir1-4* roots supplied with NH<sub>4</sub><sup>+</sup>. As a result, the difference in auxin activity profiles between the cortex and the epidermis in *eir1-4* was less pronounced than in wild type roots (Fig. 3d compared to Fig. 3b and Fig. S4a). On NO<sub>3</sub><sup>-</sup>, overall profiles of auxin activity in epidermis and cortex of *eir1-4* followed similar trends, characterized by shallow slope along the longitudinal root growth axis (Fig. 3e, Fig. S4b). Importantly, expression pattern of the auxin insensitive mDII-Venus reference construct remained largely unchanged under all tested conditions in both wild type and *eir1-4* (Fig. S4c, d). Altogether, our results point at an important role of PIN2 dependent basipetal auxin transport in adjustment of auxin activity pattern in roots to specific N conditions.

### ***PIN2 mediates root growth adaptation to nitrogen resources***

To further examine the role of PIN2 mediated basipetal auxin transport in root growth adaptation to different sources of N, *eir1-4* and *eir1-1* mutant alleles of *PIN2* were analyzed.

Unlike in wild type, no significant increase in root length was detected 1 DAT in either *eir1-4* or *eir1-1* seedlings on  $\text{NO}_3^-$  when compared to  $\text{NH}_4^+$  supplemented medium (Fig. S5a). Closer inspection of the RGR in real time using vertical confocal - root tracking set up showed that after transfer on  $\text{NH}_4^+$  growth of the *eir1-4* roots stabilized at  $1.47 \pm 0.041 \mu\text{mmin}^{-1}$  and  $1.35 \pm \mu\text{mmin}^{-1}$  during light and dark period, respectively. However, no significant increase of RGR after transfer to  $\text{NO}_3^-$  containing medium could be observed (Fig. 4a). These results strongly support an essential role of PIN2 mediated basipetal auxin transport in rapid adjustment of root growth to form of nitrogen source.

To explore whether *eir1-4* root growth adapts to different forms of N, elongation patterns of epidermal and cortex cells were analyzed. Measurements of cell lengths along the longitudinal growth axis of *eir1-4* roots supplied with  $\text{NH}_4^+$  revealed that unlike in Col-0, epidermal cells undergo gradual, steady elongation growth comparable to that in cortex. Notably, patterns of cortex and epidermal cell growth in *eir1-4* appear more synchronous than in wild-type roots on  $\text{NH}_4^+$  (Fig. 4b versus Fig. 1c). In *eir1-4* roots 12 HAT from  $\text{NH}_4^+$  to  $\text{NO}_3^-$  supplemented medium we observed largely synchronized pattern of elongation in both epidermal and cortex cell files, characterized by gradual, steady increase of cell length similar to these observed in Col-0 (Fig. 4c and Fig. 1d). Consistently with a more synchronous pattern of epidermal and cortex cell growth in both N regimes, no significant differences in frequency of mitotic events between epidermis and cortex were found in *eir1-4* roots on medium supplied with either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  (Fig. 4d).

Overall, loss of PIN2 activity interfered with enhancement of root growth in response to  $\text{NO}_3^-$  provision and affected the establishment of tissue specific growth patterns typically adopted by Col-0 roots supplied with different sources of N. Altogether, these results indicate that PIN2 mediated basipetal auxin transport plays an important function in acquiring distinct root growth patterns during adaptation to different N sources.

### ***PIN2 delivery to the plasma membrane and polarity is adjusted in response to form of nitrogen source***

To explore the mechanisms underlying PIN2 function in root growth adaptation to different N sources we examined its expression, abundance at the plasma membrane (PM) and subcellular trafficking in roots supplied with  $\text{NH}_4^+$  or  $\text{NO}_3^-$ . RT-qPCR analyses of 7 DAG roots grown on  $\text{NH}_4^+$  and transferred to media supplemented with either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  for 1, 6 and 48 hours did not reveal any significant changes in *PIN2* transcription in any of the tested conditions (Fig. S6a). Likewise, expression of neither the *PIN2::nlsGFP* nor the *PIN2::GUS* reporter was

affected by different N source (Fig. S6b). Interestingly, monitoring of *PIN2::PIN2-GFP* transgenic seedlings revealed significantly increased abundance of the PM located PIN2-GFP in epidermal and cortex cells of roots supplied with  $\text{NO}_3^-$  when compared to  $\text{NH}_4^+$  (Fig. 5a). Furthermore, in cortex cells at the transition zone of  $\text{NO}_3^-$  supplied roots, besides expected localization at the apical PM<sup>39</sup>, enhanced lateralization of PIN2-GFP to the inner and outer PMs could be detected (Fig. 5b, Fig. S6d). Immunolocalisation using PIN2-specific antibodies is fully consistent with the observations of PIN2-GFP and ruled out possible interference with fluorescence of GFP reporter by different N source (Fig. S7a-c). Hence, substitution of  $\text{NH}_4^+$  by  $\text{NO}_3^-$  seems to affect PIN2 at post-transcriptional rather than at transcriptional level.

PIN proteins constantly recycle between the PM and endosomal compartments, thus their abundance at the PM is largely dependent on a balance between endo- and exocytosis<sup>47,48</sup>. Hence, we explored whether modulation of PIN2 subcellular trafficking is the mechanism involved in adjustment of the PIN2 pattern in response to the available N source. In epidermal cells on  $\text{NH}_4^+$  when compared to  $\text{NO}_3^-$  supplied roots, the ratio between intracellular versus PM-located PIN2-GFP was shifted in favor of intracellular localization and frequently endosomal vesicles with PIN2-GFP signal could be detected (Fig. 5c, Supplemental video 3). This indicates that dynamics of PIN2 subcellular trafficking might be altered on the basis of the N source. To assess whether in  $\text{NH}_4^+$  versus  $\text{NO}_3^-$  supplied roots, accumulation of PIN2 at the PM is the result of a changed balance between endo- and exocytosis, we analyzed *pPIN2::PIN2-Dendra* seedlings. The irreversible photo-conversion of the Dendra fluorochrome by UV light from its green form to red allowed us to follow the impact of the N source on the subcellular fate of PIN2. By monitoring the PIN2-Dendra signal after photo-conversion (red signal) versus the newly synthesized PIN2-Dendra (green signal) in real time we could evaluate the kinetics of PIN2 internalization from the PM and delivery of the *de novo* synthesized PIN2-Dendra proteins. We found that the kinetics of the photo-converted PIN2-Dendra (red signal) at the PM in either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  were not statistically different, indicating that the internalization of PIN2 is not affected by the N source. Nevertheless, recovery of the newly synthesized PIN2-Dendra (green signal) was significantly enhanced in  $\text{NO}_3^-$  when compared to  $\text{NH}_4^+$  supplied roots (Fig. 5d, Fig. S6c). Considering that different sources of N did not have significant impact on *PIN2* transcription (Fig. S6a), these results suggest that recycling or secretion of PIN2 to the PM is more promoted in  $\text{NO}_3^-$  supplied roots than in those on  $\text{NH}_4^+$ . To further examine the impact of N source on the delivery of PIN2 to the PM we performed Fluorescence Recovery After Photobleaching (FRAP) analyses on the apical membrane of the cell. Lateral diffusion of PIN proteins at the PM is negligible<sup>49</sup>, thus PIN2-

GFP signal recovery after photobleaching can be correlated with the delivery of PIN2 protein to the PM. In epidermal cells of  $\text{NO}_3^-$  supplied roots PIN2-GFP signal recovered significantly faster as compared to roots supplied with  $\text{NH}_4^+$  (Fig. 5e), thus strongly suggesting that delivery of PIN2 towards the PM is differentially regulated by specific forms of N source.

Finally, to examine whether the above described different recycling behavior of PIN2 has an impact on the establishment of its apical polar domain, we performed super-resolution imaging employing three-dimensional structured illumination microscopy (3D-SIM). In roots supplemented with either  $\text{NH}_4^+$  or  $\text{NO}_3^-$ , PIN2-GFP accumulated at the apical edge of epidermal cells to the same level. However, in  $\text{NH}_4^+$  supplemented roots, number of the PIN2-GFP positive particles decreased with distance from the cell edge significantly more than in roots supplied with  $\text{NO}_3^-$  (Fig. 5f).

In summary, these results suggest that PIN2 subcellular trafficking, and in particular the delivery of PIN2 to the PM is differentially adjusted according to the N source.

### ***Nitrogen dependent PIN2 phosphorylation fine-tunes intracellular dynamics and membrane polarity of PIN2***

Post-translational modifications including phosphorylation are regulatory cues with significant impact on the intracellular trafficking and polar membrane localization of PIN proteins<sup>50</sup>. Phosphoproteome analysis of samples with either  $\text{NH}_4^+$  or  $\text{NO}_3^-$  as their N source revealed that PIN2 was among the proteins exhibiting an altered pattern of phosphorylation in response to  $\text{NH}_4^+$  (Vega et al.). Ser439 located at the very end of the PIN2 cytoplasmic loop (C-loop), was identified as a potential target for differential phosphorylation, where a reduction of phosphorylation in  $\text{NO}_3^-$  conditions was detected compared root supplied with either  $\text{NH}_4^+$  or KCl (Vega et al.). Multiple sequence alignment revealed that this Ser439 residue is highly specific to PIN2 (Fig. S6e). Interestingly, amino acid sequence alignment of PIN2 orthologues indicated that Ser439 is highly conserved in the PIN2 or PIN2-like clade across plant species including gymnosperms, mono- and dicotyledonous plants (Fig. S6f).

To examine a role of this specific, uncharacterized phosphosite in subcellular dynamics and function of PIN2, we introduced amino acid substitutions S439D and S439A to achieve either gain- or loss- of phosphorylation status of PIN2, respectively. *PIN2::PIN2<sup>S439D</sup>-GFP* and *PIN2::PIN2<sup>S439A</sup>-GFP* constructs were introgressed into the *eir1-4* mutant line. The phospho-variant version PIN2<sup>S439D</sup>-GFP, like PIN2-GFP, accumulated at the PM of epidermal and cortex cells significantly more in roots supplied with  $\text{NO}_3^-$  than  $\text{NH}_4^+$  (Fig. 6a, b, d). Interestingly, the amount of the PM localized phospho-dead PIN2<sup>S439A</sup>-GFP in  $\text{NH}_4^+$  -supplied roots was

significantly higher when compared to PIN2-GFP and PIN2<sup>S439D</sup>-GFP, and only a slight increase in epidermal cells could be detected in response to NO<sub>3</sub><sup>-</sup> supply (Fig. 6a, c, d). Furthermore, in cortex cells at the TZ, reduced lateralization of PIN2<sup>S439D</sup>-GFP on NO<sub>3</sub><sup>-</sup> supplemented medium could be observed. PIN2<sup>S439A</sup>-GFP lateralized towards outer and inner PMs irrespective of the N source thus phenocopying the PIN2-GFP pattern in NO<sub>3</sub><sup>-</sup> supplied roots (Fig. 6e-g). Altogether, these results suggest that phosphorylation status of PIN2 on S439 account for fine-tuning of PIN2 trafficking towards the PM and polarity establishment under varying N sources.

### ***Nitrogen dependent PIN2 phosphorylation fine-tunes PIN2 mediated root growth***

Next, we examined the impact of PIN2 phosphorylation status on the root growth adaptations to different N source. To evaluate functionality of PIN2-GFP constructs with phosphosite substitutions, we analyzed their ability to rescue the agravitropic phenotype of *eir1-4*. PIN2::S439D-GFP as well as PIN2::S439A-GFP constructs were able to rescue the agravitropic phenotype of the *eir1-4* mutant (Fig. S8a), indicating that the overall activity was maintained in both mutated variants. However, measurements of roots 6, 24 and 96 HAT on either NH<sub>4</sub><sup>+</sup> or NO<sub>3</sub><sup>-</sup> supplemented media revealed that modulation of PIN2 phosphorylation status interfere with the flexible adjustment of root growth to N source. Roots of PIN2::S439D-GFP;*eir1-4* exhibited enhanced growth already 6 hours after transfer on NO<sub>3</sub><sup>-</sup> when compared to NH<sub>4</sub><sup>+</sup> supplemented medium (Fig. 7a); however, when compared to control seedlings the enhancement of root growth by NO<sub>3</sub><sup>-</sup> was less pronounced 4 DAT (Fig. S8b). This suggests that PIN2<sup>S439D</sup>-GFP is partially able to mediate distinct root growth responses to different N sources. Roots of *eir1-4* expressing PIN2::S439A-GFP exhibited delay in adjusting growth to NO<sub>3</sub><sup>-</sup> provision and no significant increase in length 6 and 24 HAT to NO<sub>3</sub><sup>-</sup> when compared to NH<sub>4</sub><sup>+</sup> could be detected (Fig. 7a; S8b).

Intriguingly, although PIN2::S439D-GFP partially recovered the ability of *eir1-4* roots to adjust elongation growth to N source, in depth analysis of epidermal and cortex cell files revealed intriguing differences when compared to control roots. In PIN2::S439D-GFP;*eir1-4* roots, irrespective of the N source, length of epidermal cells steeply increased with distance from QC, whereas cortex cells underwent slow steady elongation. Similar asynchronous growth patterns in epidermal and cortex cell files were observed in NH<sub>4</sub><sup>+</sup>, but not in NO<sub>3</sub><sup>-</sup> supplied PIN2::eir1-4 and Col-0 roots, indicating that PIN2::S439D-GFP is not able to recover all aspects of root adaptation to varying N supply (Fig. 7b,c compared to Fig. S8c, Fig.1c). In PIN2::S439A-GFP roots irrespective of the N

source, shallow slope of epidermal cell length was detected, which resulted in synchronized growth patterns of epidermal and cortex cell files, resembling those observed in *PIN2::PIN2-GFP, eir1-4* and Col-0 roots supplied with  $\text{NO}_3^-$  (Fig. 7d, e compared to Fig. S8c, Fig. 1d). Thus, *PIN2::PIN2<sup>S439A</sup>-GFP, eir1-4* roots supplemented with  $\text{NH}_4^+$  acquired features typical for Col-0 roots supplied with  $\text{NO}_3^-$ .

In summary, the *PIN2<sup>S439D</sup>-GFP* phospho-variant is lacking the enhanced elongation growth of *eir1-4* roots, but it is unable to synchronize the patterns of epidermis and cortex elongation in response to  $\text{NO}_3^-$ . Unlike *PIN2<sup>S439D</sup>-GFP*, *PIN2<sup>S439A</sup>-GFP* is unable to rescue sensitivity of *eir1-4* roots to  $\text{NO}_3^-$  stimulatory effect on root elongation growth and to synchronize the patterns of epidermis and cortex elongation growth, irrespective of N source. Taking together, these results indicate that N dependent regulation of phosphorylation status of PIN2 at S439 is a part of complex mechanism underlying root growth adaptation to specific N source, which involves coordination of tissue specific balance between cell proliferation and elongation.

### ***An experimentally-derived quantitative model predicts nitrogen-dependent coordination of root growth***

Experimental findings suggest that nitrogen-dependent fine-tuning of polar auxin transport through the regulation of PIN2 phosphorylation status could coordinate the growth of adjacent tissues and thereby steer the root growth. To mechanistically understand nutrient effect on plant root growth, we developed a multilevel computer model of epidermis and cortex tissues. The complete scheme of the model components can be found in Fig. S9 and a full description of the model is provided in the Methods section. The model integrates the experimental observations of N source dependent effects on PIN2 accumulation at the PM (Supplementary dataset 1) and previously shown auxin-dependent degradation of *PIN2<sup>S439D</sup>*<sup>51,52</sup>. As a source of auxin we tested two likely scenarios *i.*) a uniform source of auxin along the epidermis (Model A) or *ii.*) flow of auxin from lateral root cap (LRC) and QC into epidermis<sup>53,54</sup> (Model B). In addition, other less favorable scenarios were also tested (see Methods and Fig. S10f). Importantly, PIN2 polarity and auxin distribution as well as cell length and number of cell division resulted purely from predictions of the model. To test our models, we compared experimental observations of PIN2 distributions (Supplementary Video 6, Supplementary data set 1), cell length measurements (Fig. 1, Supplementary dataset 1) and auxin content (Fig. 2, Supplementary data set 1) with the predicted by computer model simulations. The initial Model A failed to recapitulate experimental data (Fig. S10b-d), indicating that the auxin source

assumption may not be correct and/or there are missing components, which were not considered in this model. Model B, which unlike Model A, integrates flow of auxin from the QC and the LRC into the epidermis, and in addition, it implements correlation between cell distance from the QC with both increased PIN2 trafficking and PIN2 degradation (Fig. S10e), was able to recapitulate PIN2 and auxin distributions as well as cell length across the meristem (Supplementary Fig. 10a-d and 10f). To comprehend a necessity for these two essential components in our model, we closely inspected the relation between auxin activity levels and PIN2 fluorescence in our experimental dataset in roots supplemented with  $\text{NO}_3^-$  or  $\text{NH}_4^+$ . Our analysis revealed that for the same auxin activity two different PIN2 levels were observed in both the cortex and the epidermis that was dependent on distance from the QC - a component missing in Model A (Fig. S10a). This eminently bi-stable feature was important to guarantee the synchrony of cell elongation between adjacent tissues as this feature was compromised in  $\text{NH}_4^+$  grown roots that showed an asynchronous elongation of adjacent cortex and epidermal cells (Fig. S10a). Notably, Model B could successfully capture this relation (Fig. S10c, d). Finally, we coupled auxin activity to cell division and elongation and simulated our root model in both  $\text{NH}_4^+$  and  $\text{NO}_3^-$  regimes (Fig. 8b). As for previous simulations, the computer model of root growth does not include neither fixed auxin levels nor pre-patterned PIN2 polarization and was capable of recapitulating *in planta* root growth patterns in those different N sources (Fig. 8b, Supplementary Videos 7 and 8). Furthermore, model predictions such as lateral auxin distribution (Fig. 8c), meristem length (Fig. 8d) and proliferation dynamics (Fig. 8e) are in a fair agreement with experimental results (Figs. 1 and 2). Importantly, our model predicts mechanistic principles of the growth in synchrony such as coordinated cell divisions in both epidermis and cortex tissues further away from QC (Fig. 8e) and lateral auxin transport through PIN2 between cortex and epidermis near the transition zone (Fig. 8c). Mechanisms that trigger the transition from meristematic activity to cell elongation are not well understood<sup>55</sup>. Auxin plays a fundamental role in the establishment of the TZ<sup>56,57</sup>. Our model could predict a precise threshold of auxin levels that was necessary to determine the transition to elongation. This auxin threshold is dynamic as it depends on the actual N source; in particular, higher levels of auxin were required to advance cell elongation on  $\text{NO}_3^-$  (Fig. 8f). Taken together, we have developed a quantitative experimentally-supported computer model of root growth in different N sources that was capable of recapitulating all experimental observations as well as generating new predictions that could broaden our understanding of root growth mechanisms in the dynamic environment.

## Discussion

Ammonium and nitrate represent major inorganic forms of N absorbed by plants. Since the distribution of these N sources in the soil is very heterogeneous<sup>58</sup>, plants tend to maximize the N exploitation by flexible modulation of root system architecture<sup>59</sup>. Although distinct impacts of  $\text{NH}_4^+$  and  $\text{NO}_3^-$  on the root system growth and development have been already demonstrated<sup>6</sup>, molecular mechanisms how spatio-temporal changes in N resource impact on root growth are scarcely described.

Root growth is determined by the production of new cells at the apical meristem and their rapid elongation need to be well coordinated across diverse cell types of the root organ. Conversion from proliferative to elongation phases occurs as cells pass through the TZ where they undergo complex cyto-architectural re-arrangement<sup>57</sup>. Hence, alterations of root growth kinetics might result from modulation of any of these growth-determining processes. We show that replacement of  $\text{NH}_4^+$  for  $\text{NO}_3^-$  has a rapid impact on root growth kinetics and in particular progression of cells through individual root zones. While in roots supplied with  $\text{NH}_4^+$ , proliferative capacity of epidermal cells is attenuated in closer distance to the QC, which led to their earlier and rapid transition to elongation phase when compared to cortex, provision of  $\text{NO}_3^-$  promotes proliferation and steady elongation of epidermal cells, which results in well-synchronized growth patterns of epidermis and cortex. Hence, adaptation of primary roots to different sources of N encompass a tissue specific modulation of cell proliferation and cell growth kinetics.

Auxin is an essential patterning cue during plant growth and development. A number of recent studies have demonstrated that levels and distribution of this hormone have instructive function in many aspects of root growth including the root apical meristem patterning, its size determination, transition of meristematic cells into the elongation phase and capacity of cells to elongate<sup>55,60,61</sup>. Whereas the exit of cells from meristematic zone was associated with local auxin minima that has been proposed to define the transition zone<sup>60</sup>, increase of auxin signaling along the longitudinal root growth axis correlated with cell wall acidification as a potential driving force of cell elongation<sup>62</sup>.

Experimental measurements supported by a quantitative computational model indicate that adjustment of root growth dynamics in different N regimes is dependent on the precise modulation of auxin transport routes between cortex and epidermis. The steep increase of auxin activity correlating with earlier attenuation of proliferation activity in the epidermis and transition of cells into the elongation phase was eminent in roots grown on  $\text{NH}_4^+$ . In contrast,

shallow slopes of the auxin activity in both epidermis and cortex corresponded with delayed, gradual transition of epidermal cells into elongation phase in roots supplemented with  $\text{NO}_3^-$ , showing a tight growth synchronization with adjacent cortex tissues. Based on these observations we demonstrate that a flexible modulation of auxin activity in response to varying sources of N is largely consistent with described impact of auxin on key events defining root growth such as transition into elongation growth and kinetics of elongation.

Delivery of auxin in outer tissues including the cortex and the epidermis is largely mediated by the PIN2 auxin efflux carrier<sup>43,44</sup>. While PIN2 dependent basipetal transport of auxin is instructive for elongation growth and root gravity bending<sup>63</sup>, PIN2 mediated reflux to inner tissues has been associated with maintenance of root meristem size<sup>39</sup>. Measurements of the auxin transport revealed that replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$ , significantly enhances flow of auxin in the basipetal direction which correlates with increased PIN2 activity near the transition zone. Loss of PIN2 activity not only interferes with the  $\text{NO}_3^-$  stimulated transport of auxin towards the shoot, but also severely affects adaptive responses of roots to this N source. Furthermore, model predictions based on these experimental measurements suggest a bi-stable relationship between auxin levels and PIN2 activity and cell elongation that is enhanced in  $\text{NO}_3^-$ , which could explain why roots grown on nitrate can coordinate their growth by passing auxin between cortex and epidermal cells in a synchronous manner. Furthermore, our model confirmed the necessity for self-emerging communication between cortex and epidermis via auxin with quantitative computer simulations of root growth under different N conditions.

Dynamic, N source dependent accumulation and polarization of PIN2 at the PM, but unchanged *PIN2* transcription, pointed at post-transcriptional regulatory mechanism underlying adaptation of basipetal auxin transport to N supply. Replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$  promoted accumulation of PIN2 at the apical PM of epidermal and cortex cells as well as to the lateral sides.

Phosphorylation has been recognized as a prominent posttranslational modification of PIN proteins that determines their polar membrane localization and activity<sup>64</sup>. Unexpectedly, genome-wide analysis of the phosphoproteome during early phases of root adaptation to provision of  $\text{NO}_3^-$  (Vega et al.) retrieved PIN2 among differentially phosphorylated proteins. Serine 349 of PIN2 in *Arabidopsis*, found to undergo a rapid de-phosphorylation after replacement of  $\text{NH}_4^+$  by  $\text{NO}_3^-$ . The PIN2S439 phosphosite was not completely unknown: it was originally identified as differentially phosphorylated during lateral root morphogenesis<sup>65</sup>. It is positioned in the hydrophilic loop domain of the PIN2 protein and is an evolutionarily conserved residue in the PIN2 or PIN2-like clade across species including gymnosperms,

mono- and dicotyledonous plants, suggesting that PIN2 might be universally involved in other plant species adaption strategies to the changing N sources by means of its post-translational (phosphorylation) mechanism. The functional characterization of PIN2 and its phospho-variants suggests that N source dependent regulation of PIN2 phosphorylation status has a direct impact on the flexible adjustment of PIN2 membrane localization and polarity, and thereby adaptation of root growth to varying forms of N supply.

Statistical significance was evaluated with ANOVA at  $p < 0.05$ .

**Figure 5. PIN2 protein abundance, polarity and vacuolar trafficking in roots on ammonium or nitrate containing medium. a.** Pseudo-colored, optical longitudinal cross

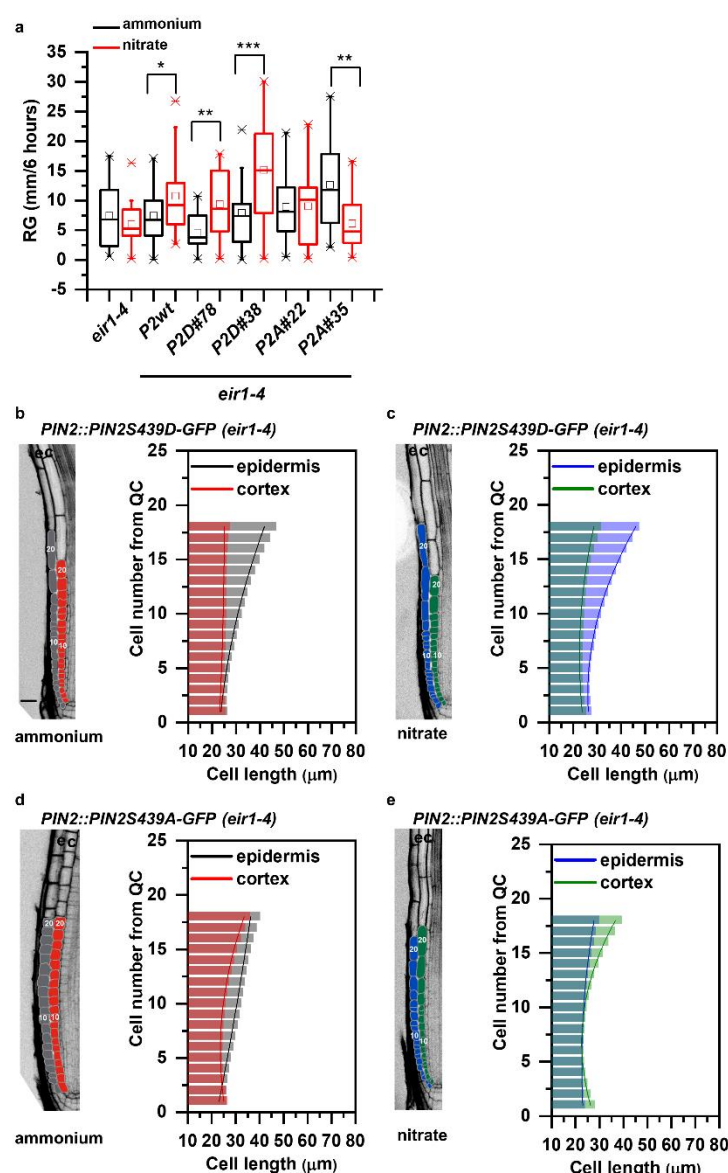

sections of 5 DAG roots expressing *PIN2::PIN2-GFP*, *eir1-4* 12 HAT to ammonium or nitrate supplemented media. “e” denotes epidermis and “c” cortex, respectively. Color code represents GFP intensity from low (blue) to high (white) values. Scale bar = 20  $\mu$ m. Box plots display the distribution of the cell membrane derived PIN2-GFP fluorescence intensity (FI) values (in arbitrary units, a.u.) on ammonium (grey, epidermis (ep) and red, cortex (co), n=15) and nitrate (blue, epidermis (ep) and green, cortex (co), n=10) grown roots. 5 cells per root were analyzed. The statistical significance was evaluated with ANOVA at  $p < 0.05$ . **b.** Higher magnification of pseudo-colored confocal images of 5 DAG old roots expressing PIN2-GFP 12 HAT to ammonium or nitrate supplemented media. “e” denotes epidermis and “c” cortex, respectively. Color code represents GFP intensity from low (blue) to high (white) values. Scale bar = 12  $\mu$ m. White stars mark PIN2-GFP protein localization on the lateral membranes. Box plots display lateralization index (fluorescent signal detected on apical/basal membranes divided by the signal value at inner/outer membranes) of roots on ammonium (n=31 cells from 6 roots) or nitrate (n=24 cells from 6 roots) supplemented medium. **c.** Pseudo-colored PIN2-GFP signal in epidermal cells of 5 DAG old roots 12 HAT to ammonium or nitrate containing media. White arrows point to PIN2-GFP containing intracellular vesicles. Box plots represent the ratio in fluorescent signal detected inside the cell vs on the membranes (FI[cyt]/FI[m]). n=6 roots per condition, 5 cells per root analyzed. Scale bar = 5  $\mu$ m. **e.** FRAP analysis of PIN2 protein mobility in *PIN2::PIN2-GFP* expressing epidermal cells 12 HAT to ammonium or nitrate. The graph shows polynomial regression fit with 95% confidence band of the mean signal recovery in the bleached region of interest (ROI) after background subtraction and normalization to photobleaching. Data are derived from 3 independent experiments, each consisting of 5 membranes from 3 different roots. Scale bar = 2  $\mu$ m. **d.** Microscopic images showing PIN2-Dendra fluorescent signal five hours after photoconversion of PIN2-Dendra into its red form. Depletion of the red signal and recovery of the green signal over a 6 hours period was followed in parallel in 5 DAG old roots 12 HAT to ammonium or nitrate supplemented media. Note the increase in the intensity of the green signal in roots transferred to nitrate. Graph represents the mean signal  $\pm$  SD (n=6 roots per condition, 20 cells per root analyzed). The experiment was repeated 3 times. Scale bar = 20  $\mu$ m. **f.** Representative 3D SIM microscopic images of 10 DAG old epidermal cells expressing *PIN2-GFP* 12 HAT to ammonium or nitrate containing media. Green dots represent PIN2-GFP on the lateral cell surface (polar domain) of epidermal cells in the transition zone. Graph represents the number of GFP positive spots along a 30  $\mu$ m long region starting at the apical side of the cell (8 cells per 4 roots and 9 cells per 4 roots) were

analyzed per treatment, experiment was done 3 times. Note the effect of ammonium versus  
nitrate on the distribution of the PIN2-GFP spots.

**Figure 6. Impact of Ser439 on PIN2 localization in roots supplemented with ammonium or nitrate.** **a - c.** Pseudo-colored, optical longitudinal cross sections of 5 DAG roots expressing (a) PIN2-GFP (*PIN2::PIN2-GFP*, *P2wt*) (b) PIN2S439D-GFP (*PIN2::PIN2S439D-GFP*, *P2D*) and (c) PIN2S439A (*PIN2::PIN2S439A-GFP*, *P2A*) - all in *eir1-4* background – 12 HAT to ammonium or nitrate supplemented media. “e” denotes epidermis and “c” cortex, respectively. Color code represents GFP intensity from low (blue) to high (white) values. Scale bar = 50 μm. **d.** Box plots display the distribution of the cell membrane derived PIN2-GFP fluorescence intensity (FI) values (in arbitrary units, a.u.) in roots transferred to ammonium ((grey, epidermis (ep) and red, cortex (co) and to nitrate (blue, epidermis (ep) and green, cortex (co)). 5 cells per roots were analyzed in at least 9 roots per genotype per treatment. The statistical significance was evaluated with ANOVA at  $p < 0.05$ . **e and f.** Microscopic images of 5 DAG old roots expressing (e) PIN2S439D-GFP and (f) PIN2S439A-GFP 12

HAT to ammonium or nitrate amended media. “e” denotes epidermis and “c” cortex, respectively. White arrows point to PIN2-GFP protein localization on the lateral membranes. **g.** Box plots display lateralization index (fluorescent signal detected on apical/basal membranes vs inner/outer membranes) of *P2wt*, *P2D* and *P2A* roots transferred to ammonium (grey) or nitrate (red) supplemented medium. At least 24 cells from 5 roots were analyzed per genotype per treatment. The statistical significance was evaluated with ANOVA at  $p < 0.05$ .

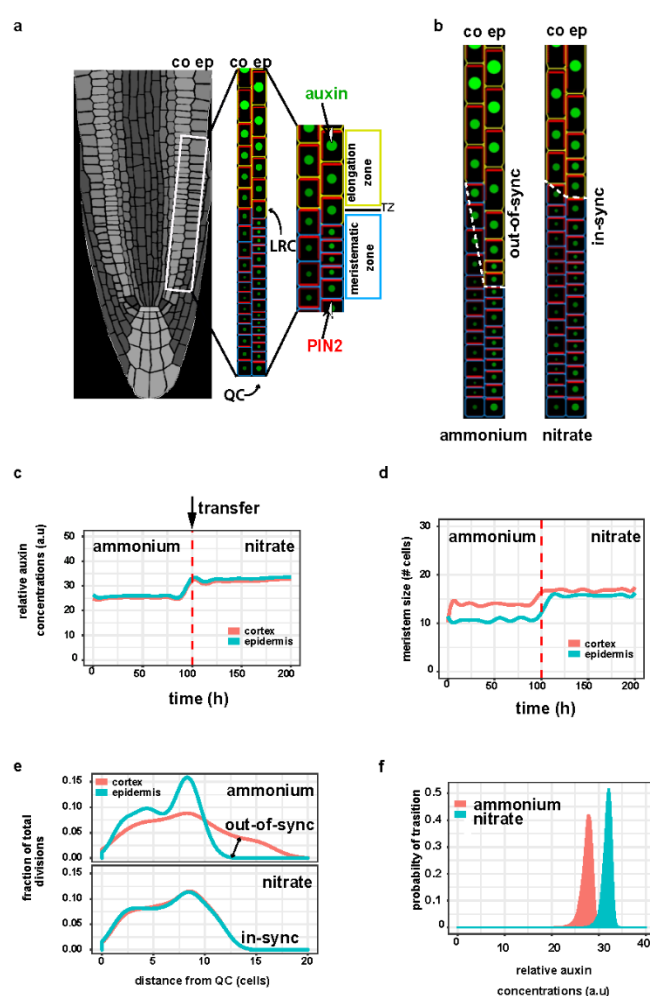

**Figure 7. Impact of PIN2S439 phospho-variants on the adaptation of the primary root growth to ammonium or nitrate provision.** **a.** Box plot representation of root growth (μm/6 hours) of *eir1-4*, Col-0, *PIN2::PIN2-GFP* (*P2wt*), two independent *PIN2::PIN2S439D-GFP* (*P2D*) lines (#78 and #38) and two independent *PIN2::PIN2S439A-GFP* (*P2A*) lines (#22 and #35) transferred to ammonium or nitrate containing medium. At least 10 roots were analyzed

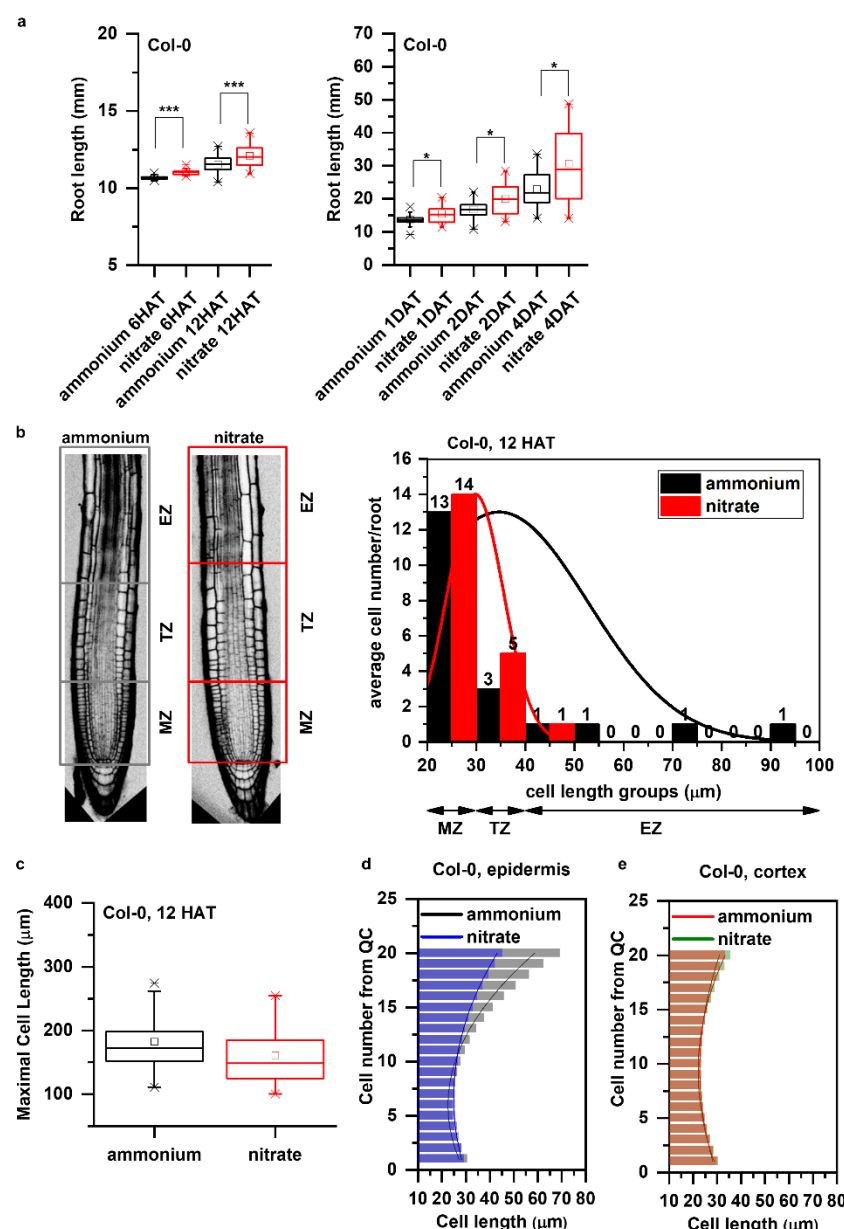

per genotype per treatment. The statistical significance was evaluated with ANOVA at  $p < 0.05$ .

**b - e.** Optical, longitudinal sections of 5 DAG old roots expressing *PIN2S439D-GFP* (**b and c**) and *PIN2S439A-GFP* (**d and e**) 12 HAT to ammonium (**b and d**) or nitrate (**c and e**) supplemented media. The first 20-20 epidermal and cortex cells (from quiescent center (QC)) are highlighted in grey and in red on ammonium (**b and d**) and in blue and green on nitrate (**c and e**), respectively. Scale bar = 30  $\mu\text{m}$ . Column bars denote the geometric mean of cell length at the respective positions. Lines represent a polynomial regression fit, with calculated slopes between cells 10 and 20 of ammonium-*PIN2S439D*-epidermis:  $1.38867 + 0.03079$ , ammonium-*PIN2S439D*-cortex:  $0.05689 + 0.00497$ , nitrate-*PIN2S439D*-epidermis:  $1.92749 + 0.0727$ , nitrate-*PIN2S439D*-cortex:  $0.66477 + 0.03592$ , ammonium-*PIN2S439A*-epidermis:  $0.7164 \pm 0.00565$ , ammonium-*PIN2S439A*-cortex:  $1.09064 \pm 0.05609$ , nitrate-*PIN2S439A*-epidermis:  $0.53796 \pm 0.0249$ , nitrate-*PIN2S439A*-cortex:  $1.61118 \pm 0.09541$ . Data are derived from 3 independent experiments; at least 5 roots were analyzed in each case.

**Figure 8. Dynamic computer model of root growth predicts nitrogen source dependent effect on cell growth dynamics, auxin distribution and root zonation.** **a.** Schematics of the root model with epidermis (ep) and cortex (co) tissues. Meristematic and elongating cells are shown with blue and yellow walls, respectively. Auxin levels are represented by green circle size and red bars reflect the PIN2 amounts. Auxin is supplied from Lateral Root Cap (LRC) and QC (Model B) **b.** Steady state snapshots from model simulation with ammonium (left panel) and with nitrate (right panel). Note out-of-sync growth patterns (dashed white line) in ammonium. **c and d.** Model simulation representing the effect of the transition from ammonium to nitrate (denoted by a red dashed line) on the relative level of auxin (C) and meristem size measured as distance from QC (D). **e.** Model predictions display the fraction of total cell division events per cell in the meristem along in the two N source. Note cell division is out-of-sync in ammonium, producing altered growth of the root. **f.** Experimentally derived relative auxin level threshold triggering cell elongation depends on the actual N content of the root.

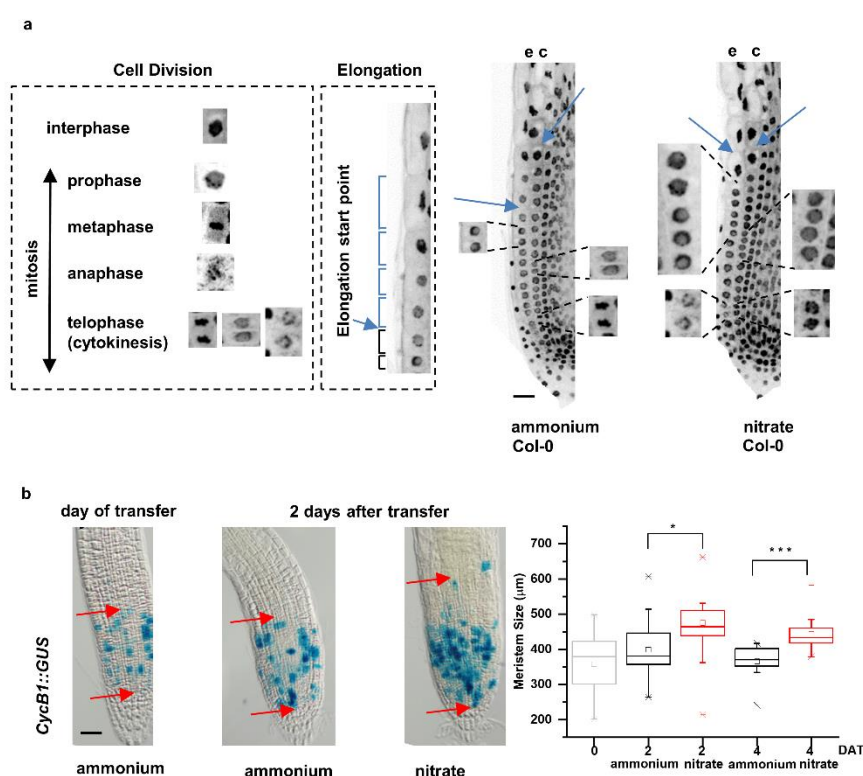

**Supplementary Figure 1 related to Figure 1. Additional data supporting the distinct growth kinetics of Col-0 roots transferred to ammonium or nitrate supplemented media.**

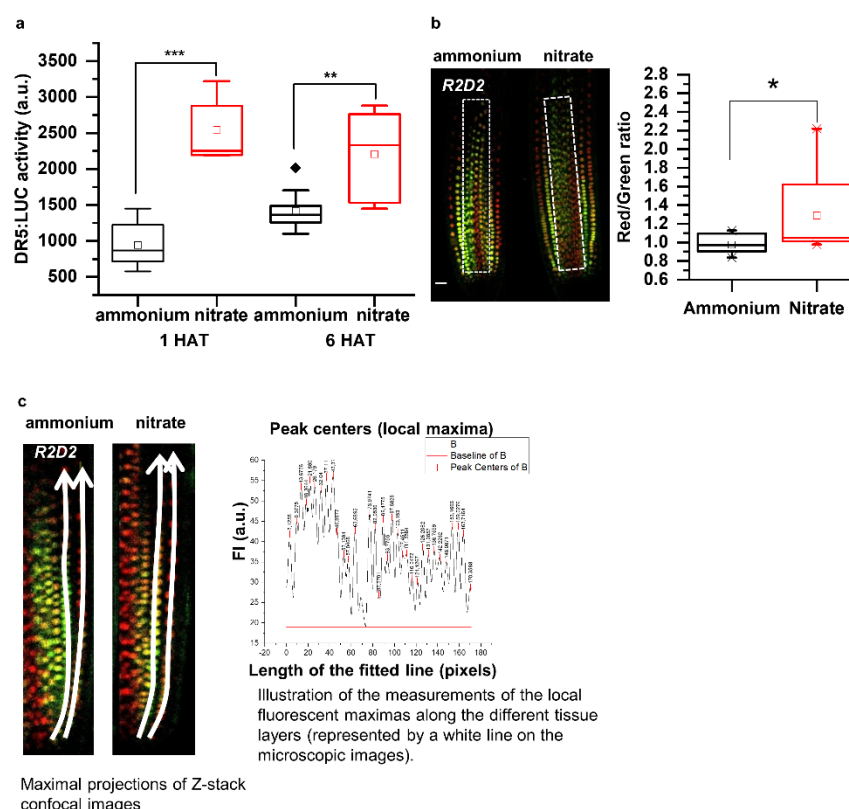

**a.** Primary root length (mm) of Col-0 seedlings 6 and 12 HAT and 1, 2, 4 days after transfer (DAT) to ammonium (black) or nitrate (red) supplemented medium. At least 34 roots were measured per time point per treatment. The statistical significance was evaluated with ANOVA at  $p < 0.05$ . **b.** On the left, schematic representation of distinct root zones: Meristematic Zone (MZ), Transition Zone (TZ, which is interpolated between the apical meristem and the subapical elongation zone) and Elongation Zone (EZ). Boxes highlight the borders of the specified root zones (grey box for ammonium and red for nitrate). On the right, Col-0 epidermal cells length was measured along the root tip (from QC), grouped based on their cell length (x

axis) and were plotted against the average cell number per group per root (y axis) in both conditions (ammonium, black and nitrate, red). Note the higher cell number in case of nitrate (red) in the group (30-40  $\mu\text{m}$ , representing TZ). Data are derived from 3 independent experiments, total number of analyzed roots are n=18 in each case. **c.** Maximal cell length (measured at the end of the elongation zone) of Col-0 roots 12 HAT either to ammonium (black) or nitrate (red). 13 roots per treatment, 3 cells per root were analyzed. **d and e.** Comparison of cell length measurements along epidermis (**d**) and cortex (**e**) upon ammonium (black and red) and nitrate (blue and green) treatments. Column bars denote the geometric mean of cell length at the respective positions. Lines represent a polynomial regression fit. Data are derived from 3 independent experiments, total number of analyzed roots are n=18 in each case.

**Supplementary Figure 2 related to Figure 1. Additional data supporting the distinct division patterns in Col-0 roots on media supplemented with different nitrogen source. a.** On the left, schematic representation of the different cell division phases of DAPI stained Col-0 roots and an illustration of how the onset of cell elongation was marked. On the right, DAPI stained confocal microscopic images of Col-0 roots 12 HAT to ammonium or nitrate containing medium. Mitotic events are displayed along epidermis (e) and cortex (c). Blue arrows point to the first elongating cells. Scale bar = 50  $\mu\text{m}$ . **b.** Bright field microscopic images of *GUS*

791 expressing roots driven by *CycB1* promoter. Blue spots mark *CycB1* promoter activity. Red  
 792 arrows point to the beginning and to the end of GUS expressing area (meristem size). Scale bar  
 793 = 100µm. Box plot chart represents the meristem size (µm) of *CycB1::GUS* expressing roots  
 794 on the day of transfer (0) and 2 and 4 DAT to ammonium or nitrate. Differences of the means  
 795 were calculated with a t-test (p value \* $<0.05$ , \*\*\* $<0.001$ ). At least 14 roots were analyzed per  
 796 time point per treatment.

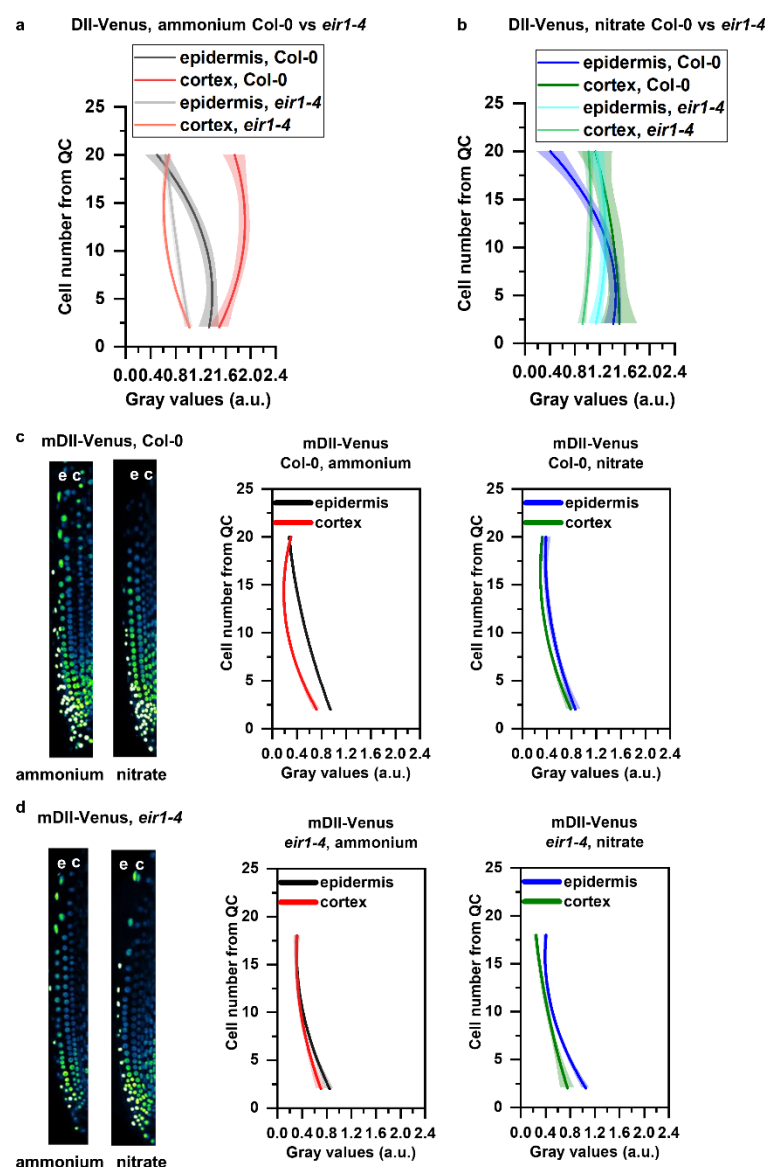

797

798 **Supplementary Figure 3 related to Figure 2. Supporting data for auxin activity and**  
 799 **distribution in roots transferred to different nitrogen sources.**

800 **a.** *DR5* activity in *Arabidopsis* roots. Box plots represents luciferase activities in *DR5::LUC*  
 801 expressing roots 1 and 6 HAT. 40 roots were collected per treatment per time points.  
 802 Experiment was repeated 3 times. Statistical differences were calculated with a t-test (p values  
 803 \*\* $<0.01$ , \*\*\* $<0.001$ ) **b.** Expression profile of the auxin-input reporter *R2D2* in the stele  
 804 (labeled with “white box”) of roots 12 HAT to ammonium or nitrate containing media. Box  
 805 plots represent the quantification of the red (auxin-independent) vs green (auxin dependent)  
 806 fluorescent signal ratio in the stele. At least 13 roots were analyzed and statistical difference  
 807 was calculated with a t-test (p value  $<0.05$ ). **c.** Illustrations for *R2D2* quantification along

808 epidermal and cortical cell files. For details see the “Quantification of R2D2, DII-VENUS and  
809 mDII-VENUS fluorescence signal” in the “Methods” section.

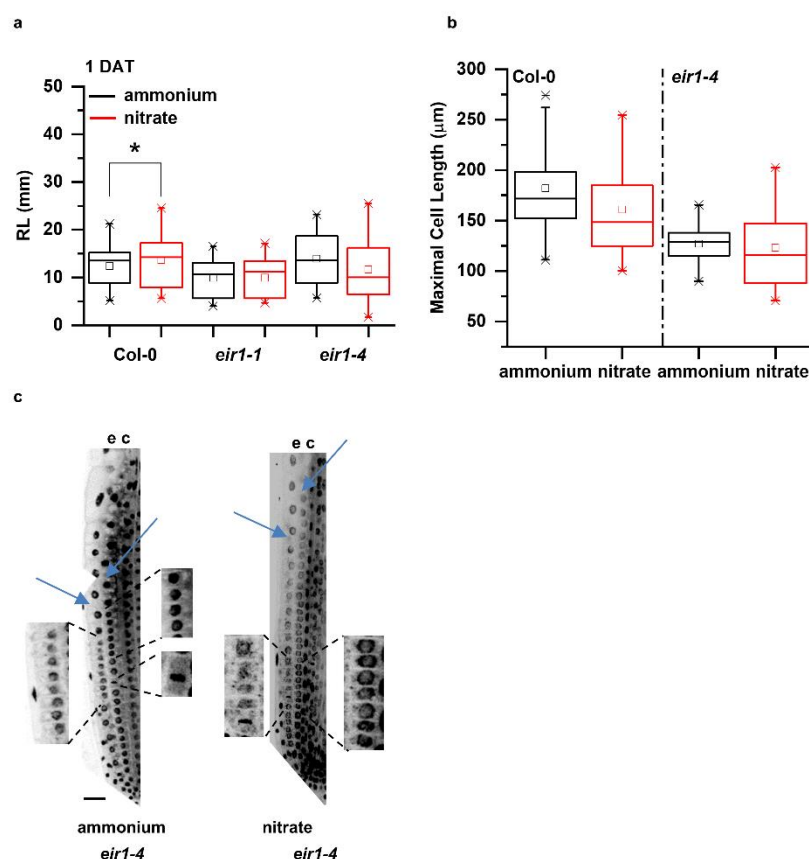

810

811 **Supplementary Figure 4 related to Figure 3. Additional data for demonstrating the**  
812 **distinct patterns of auxin distribution in Col-0 and *eir1-4* roots**

813 **a and b.** Comparison of DII-Venus fluorescent signal in Col-0 and *eir1-4* lines on ammonium  
814 (a) and on nitrate (b) transferred roots. Graphs denote normalized relative auxin levels at the  
815 respective positions. Lines represent polynomial regression fit with 95% confidence band. Data  
816 are derived from measurements of n=8 (ammonium) and n=10 (nitrate) roots of Col-0 and n=10  
817 roots of *eir1-4* per condition. **c and d.** Maximum intensity Z-stack projection images of 5 DAG  
818 old Col-0 (c) and *eir1-4* mutant (d) roots expressing the non-auxin degradable mDII-Venus  
819 reporter grown on ammonium and nitrate supplemented media 12 HAT. “e” and “c” marks

820 epidermis and cortex, respectively. Scale bar = 50  $\mu$ m. Graphs denote grey values (arbitrary  
821 units - a.u.) at the respective positions. Lines represent polynomial regression fit with 95%  
822 confidence band. Data are derived from measurements of at least 5 roots per genotype per  
823 treatment.

824

825 **Supplementary Figure 5 related to Figure 4. Additional data for demonstrating root**

826 **growth phenotypes and cell divisions in *pin2* mutants**

827 **a.** Comparison of root length of *pin2* mutants (*eir1-1* and *eir1-4*) to Col-0 on ammonium

828 (black) and nitrate (red) amended media, 1 DAT. At least 11 roots were analyzed per genotype

829 per treatment and statistical difference was calculated with a t-test (p value <0.001) **b.** Box

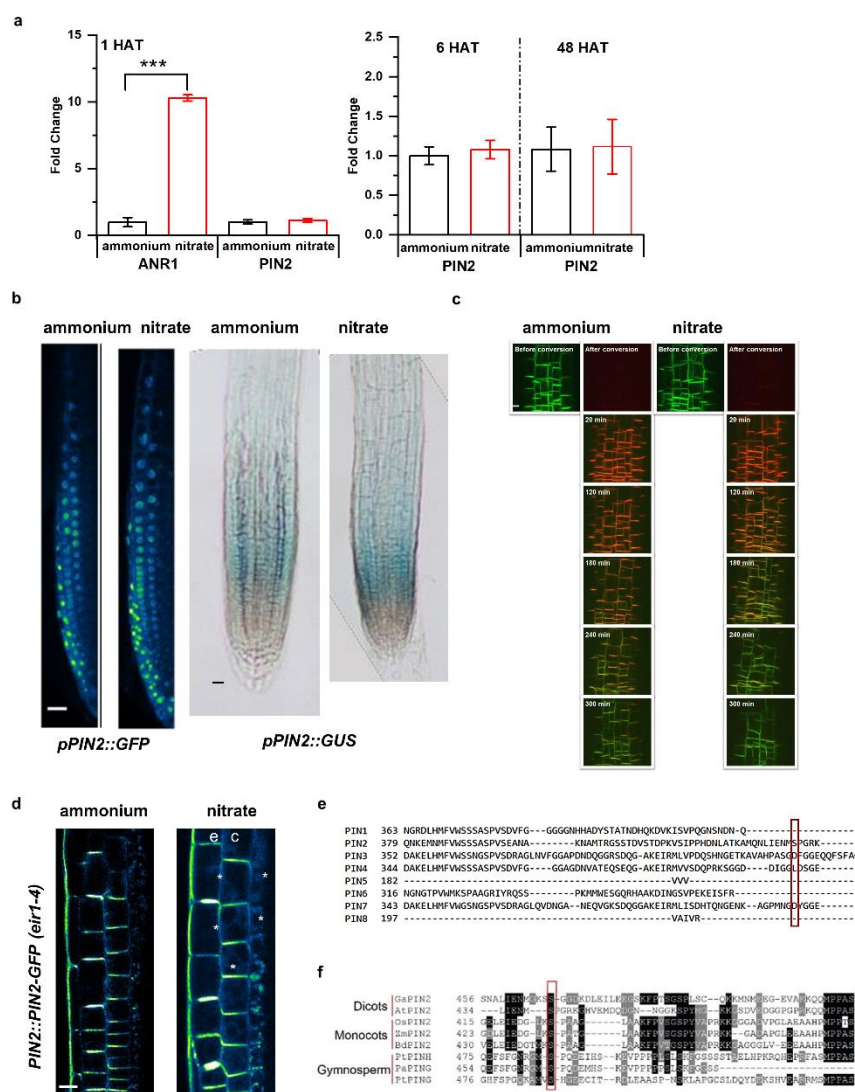

830 plots of the maximal cell length of Col-0 and *eir1-4* mutant roots 12 HAT to ammonium (black)

831 or nitrate (red). 3-3 cells in at least 13 roots were analyzed per genotype per treatment. **c.** DAPI

832 stained confocal microscopic images of *eir1-4* roots 12 HAT to ammonium or nitrate

833 containing medium. Mitotic events are highlighted along epidermis (e) and cortex (c). Blue

834 arrows point to the first elongating cells. Scale bar = 50  $\mu$ m.

## Supplementary Figure 6 related to Figure 5. Additional data supporting distinct effects of nitrogen sources on PIN2

**a.** RT-qPCR analysis of *PIN2* expression normalized to *UBQ10* (*AT4G05320*) levels in Col-0 roots 1, 6 and 48 HAT to ammonium or nitrate. As a positive control, expression of *ANR1* (nitrate responsive MADS-box transcription factor) was quantified. All RT-qPCR reactions were carried out with biological and technical triplicates. Statistical difference was calculated with a t-test (p value \*\*\*<0.001). **b.** *PIN2* promoter activity was monitored in *pPIN2::nlsGFP* and *pPIN2::GUS* expressing roots 12 HAT to ammonium or nitrate. Scale bars = 50  $\mu$ m. **c.** Confocal microscopic images of *PIN2::PIN2-DENDRA* fluorescence in the same area of the root transition zones 12 HAT to ammonium or nitrate before and after photoconversion (0, 20, 120, 180, 240, 300 min). Scale bar = 20  $\mu$ m. **d.** Multiphoton microscopic image showing polarity changes of *PIN2* expression upon nitrate treatment. “e” and “c” denote epidermis and

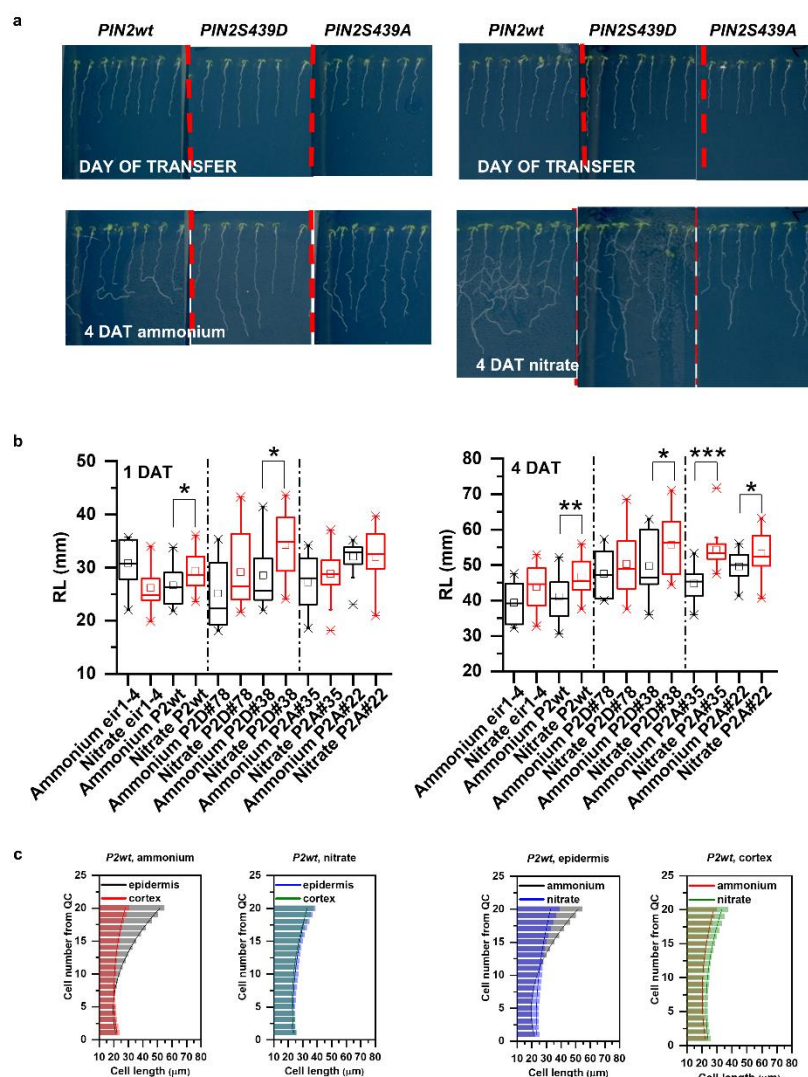

cortex respectively. White arrows mark lateralization of the PIN2-GFP signal in cortex cells (c). **e.** Protein sequence alignment of members of the *Arabidopsis* PIN protein family. Ser439 of PIN2 and the corresponding residues of other PIN family members are marked by a red box. **f.** PIN2 protein sequence alignment shows evolutionary conservation of Ser439 in representative members of Gymnosperms, Monocots and Dicots. From Gymnosperms *Picea abies* (Pa) and *Pinus taeda* (Pt) PIN2 proteins (PtPING, PtPINH, PaPING), from Monocots *Zea mays* (Zm), *Brachypodium distachyon* (Bd) and *Oryza sativa* (Os) PIN2 proteins (ZmPIN2, BdPIN2, OsPIN2) and from Dicots *Gossypium arboreum* (Ga) and *Arabidopsis thaliana* (At) PIN2 proteins (GaPIN2, AtPIN2) were used. Protein alignments were created with the MEGAX software<sup>66</sup>.

# **Supplementary Figure 7 related to Figure 5a. PIN2 immunostaining in PIN2-GFP expressing roots**

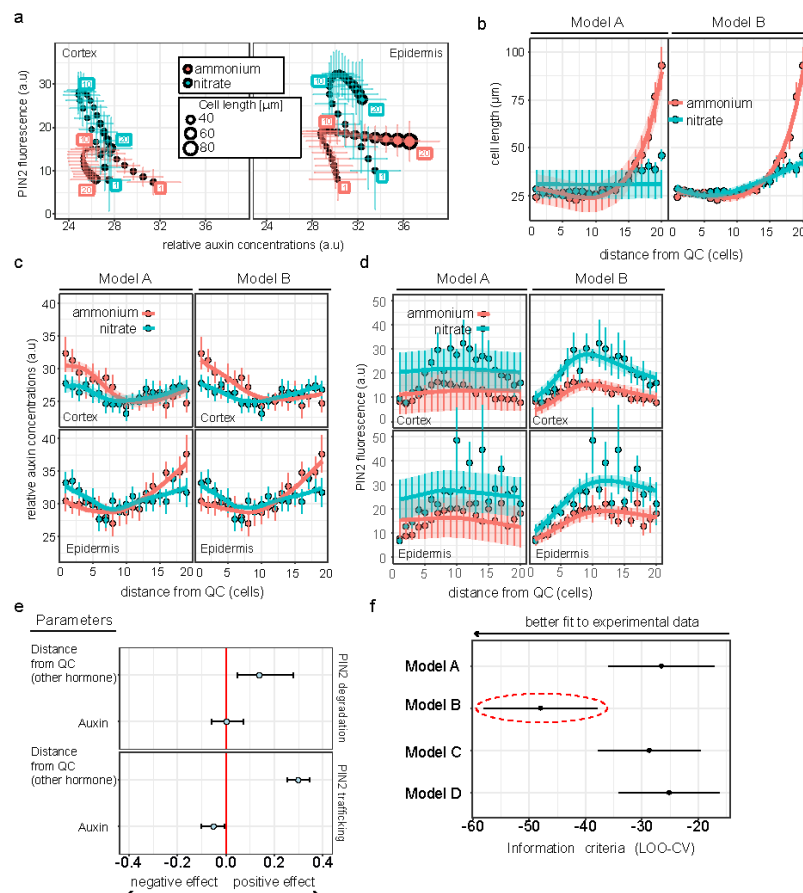

**a.** Confocal microscopic images show anti-PIN2 immunostained PIN2-GFP expressing root tips 12 HAT to ammonium or nitrate. Green and blue signal represents PIN2 and nuclear staining with DAPI, respectively. **b.** Higher magnification of anti-PIN2 immunostained PIN2-GFP expressing root in the transition zone. “e” and “c” denote epidermis and cortex, respectively. Scale bar = 25 μm. **c.** Quantification of PIN2 fluorescent signal in the immunostained, ammonium or nitrate treated roots in epidermal (ep) and cortical (co) cell files. Statistical difference was evaluated with ANOVA at p<0.05. 10 roots were analyzed per treatment.

## Supplementary Figure 8 related to Figure 7. Additional data supporting impact of PIN2S439 phospho-variants on root growth adaptation to source of nitrogen

**a, b.** Seedlings expressing *PIN2::PIN2-GFP* (*P2wt*), *PIN2::PIN2S439D-GFP* (*P2D*) and *PIN2::PIN2S439A-GFP* (*P2A*) in *eir1-4* background. Representative images of seedlings at the day of transfer and 4 DAT to ammonium or nitrate supplemented plates are shown (**a**). Quantification of root length (mm) in *eir1-4*, *PIN2wt* (*eir1-4*) and two independent *P2D* (*eir1-4*) (#78 and #38) and *P2A* (*eir1-4*) (#35 and #22) lines 1 and 4 DAT to ammonium or nitrate containing media. At least 7 roots per genotype per treatment were analyzed. Statistical difference was evaluated with a t-test (p values  $* < 0.05$ ,  $** < 0.01$  and  $*** < 0.001$ ). **c.** Comparison of cell length changes in epidermal and cortical cell files of *PIN2::PIN2-GFP* (*P2wt*) expressing roots transferred to ammonium or nitrate. Column bars denote the geometric mean of cell length at the respective positions. Lines represent a polynomial regression fit. Data are derived from measurements of 20 roots per genotype per treatment.

# **Supplementary Figure 9. Model robustness and fitting to experimental measurements. a.**

The experimentally-driven PIN2 levels in the function of relative auxin levels for cortex (left panel) and epidermis (right panel), respectively. Relative auxin levels were calculated as follows:  $\log(G/(G+R)) / -0.025$ , where G and R represent DII-Venus (green) and mDII-Tomato (red) fluorescent signals, respectively. Cell length is denoted by dot size, and the distance of the cell from the QC is labelled with consecutive numbers. Vertical and horizontal lines represent the standard error of measurements. **b-d.** Validations in two regimes demonstrate that Model B faithfully recapitulates all experimental measurements. In these plots model predictions (thick lines and shaded areas for the posterior average and 95% confidence intervals, respectively) are plotted against experimental data (dots and vertical bars for data mean and standard deviations, respectively). **e.** Parameter estimations for Model B suggest antithetic cumulative effects of auxin level and distance from QC on PIN2 dynamics. **f.** Predictive power of four models for auxin input scenario (A-D). The expected log probability density is used as information criterion. Lower information criterion indicates better posterior predictive performance, and therefore a better fit to the experiments (dashed red ellipse).

Z-stacks of 2-2 cells in the transition zone of 5-day-old *Arabidopsis* roots expressing *PIN2::PIN2-GFP* 12 HAT to either to ammonium or nitrate amended media and imaged with an Airyscan LSM800 microscope.

**Supplementary Video 4 related to Figure 7.**

Time lapse of *Arabidopsis* seedlings expressing *PIN2::PIN2-GFP* (*PIN2wt*), *PIN2::PIN2S439D-GFP* (*PIN2S439D*) and *PIN2::PIN2S439A-GFP* (*PIN2S439A*). Seedlings were grown on ammonium plates for 7 days and were transferred to ammonium containing agar plates. Plates were scanned on a daily basis with an Epson Perfection V700 flatbed scanner. Images were concatenated with Fiji.

**Supplementary Video 5 related to Figure 7.**

Time lapse of *Arabidopsis* seedlings expressing wild type *PIN2::PIN2-GFP* (*PIN2wt*), *PIN2::PIN2S439D-GFP* (*PIN2S439D*) and *PIN2::PIN2S439A-GFP* (*PIN2S439A*). Seedlings were grown on ammonium plates for 7 days and were transferred to nitrate containing agar plates. Plates were scanned on a daily basis with an Epson Perfection V700 flatbed scanner. Images were concatenated with Fiji.

**Supplementary Video 6 related to Figure 8.**

A simulation of static example model shows intercellular auxin transport via PIN2 auxin carrier.

**Supplementary Video 7 related to Figure 8.**

Simulation of asynchronous growth of epidermis-cortex tissues in ammonium condition. Related to Fig. 8b.

**Supplementary Video 8 related to Figure 8.**

Simulation of asynchronous growth of epidermis-cortex tissues in nitrate condition. Related to Fig. 8b.

C.

# Supplementary Document 1. Statistical reasoning.

**A.** Estimated marginal mean (EMM) comparisons of cell lengths in different tissues (epidermis vs cortex) at each cell position (1-20 from QC) for each treatment (ammonium vs nitrate) applied on a generalized linear model (GLM). Significant differences ( $p < 0.01$ ) are highlighted in red. **B.** EMM comparisons of cell lengths in different treatments (ammonium vs nitrate) at each cell position (1-20 from QC) for epidermis vs cortex on the same GLM model. Significant differences ( $p < 0.01$ ) are highlighted in red. **C.** A decision tree based on recursive partitioning analysis shows the hierarchical importance of each treatment, tissue and cell position variable on cell length differences.

## Methods

### Plant material

*Arabidopsis thaliana* (L.) Heynh plants were used in this work. The transgenic lines *W131Y*<sup>67</sup>, *PIN2::PIN2-GFP*<sup>68</sup> in *eir1-4* background, *PIN2::PIN2S439D-GFP*, *PIN2::PIN2S439A-GFP* (Vega et al.,) were introduced into *eir1-4* background; *PIN2::PIN2-Dendra*<sup>69</sup>, *R2D2*<sup>70</sup>, *DII-VENUS*<sup>70</sup>, *mDII-VENUS*<sup>70</sup>, *PIN2::nls-GFP*<sup>71</sup>, *DR5::LUC*<sup>72</sup>, *DR5::RFP*<sup>73</sup>, *CyclinB1::GUS*<sup>74</sup> and the T-DNA mutant line *eir1-4* were described previously. *DII-VENUS* and *mDII-VENUS* in *eir1-4* background lines were obtained by manual hand pollination of the individual lines.

### Growth conditions

Seeds of *A. thaliana* were surface-sterilized by 70% ethanol and sown on a modified Murashige and Skoog (MS) medium - Boric Acid 6.2 mg/L, Calcium Chloride (anhydrous) 332.2 mg/L, Cobalt Chloride (6H<sub>2</sub>O) 0.025 mg/L, Cupric Sulfate (5H<sub>2</sub>O) 0.025 mg/L, Na<sub>2</sub>EDTA (2H<sub>2</sub>O) 37.26 mg/L, Ferrous Sulfate (7H<sub>2</sub>O) 27.8 mg/L, Magnesium Sulfate (anhydrous) 180.7 mg/L, Molybdic Acid (disodium salt 2H<sub>2</sub>O) 0.25 mg/L, Potassium Iodide 0.83 mg/L, Potassium Phosphate (monobasic, anhydrous) 170 mg/L, Zinc Sulfate (7H<sub>2</sub>O) 8.6 mg/L – which contained 0.5mM Ammonium Succinate (Santa Cruz Biotechnology) (76 mg/L) as a nitrogen source and supplemented with 0.1% sucrose and 1% agar (Type E, Sigma A4675), pH=5.8. The nitrate amended media contained 5mM Potassium Nitrate (505 mg/L) instead of 0.5mM Ammonium Succinate. Seeds were stratified at least for 3 d and grown for 4-14 d at 21 °C in a 16 h light/8 h dark cycle.

### **Root growth and root length analysis**

7-day-old light-grown seedlings were transferred to either ammonium or nitrate amended plates and scanned on a daily basis for 7 days on an Epson Perfection V700 flatbed scanner. Root growth (root length changes over a given period of time) and root length were measured manually using Fiji (v1.52).

### **Cell elongation and cell length analysis**

Cell elongation was measured after 12 hours exposure to either to ammonium or nitrate manually with the software Fiji (v1.52).

For cell length analysis, confocal microscopic images of propidium iodide-stained *PIN2::PIN2-GFP*, *PIN2::PIN2S439A-GFP*, *PIN2::PIN2S439D-GFP*, Col-0 and *eir1-4* roots were used and the length of each cell in different cell files (epidermis and cortex) was measured manually using Fiji (v1.52).

### **Imaging and image analysis**

5 DAG seedlings were mounted on a slice of MS medium - containing either 0.5mM ammonium or 5mM nitrate - placed into a chambered coverslip (Lab-Tek) and imaged with Zeiss LSM700, LSM800 or LSM880 inverted confocal microscopes equipped either with a 20×/0.8 Plan-Apochromat M27 objective or a 40× Plan-Apochromat water immersion objective. Fluorescence signals for GFP (excitation 488 nm, emission 507 nm), YFP (excitation 514 nm, emission 527 nm), PI (excitation 536 nm, emission 617 nm) and DAPI (excitation 405 nm, emission 461 nm) were detected. A LaVision 2-Photon Inverted TriM Scope II from LaVision Biotec with a FLIM X16 TCSPC detector from LaVision Biotec equipped with a Olympus UApo N340 40xW, NA 1.15 was also used. Roots were observed 12 hours after

transfer to ammonium or nitrate supplemented media. Long time-lapse imaging was performed using a vertically oriented LSM700 microscope as described previously<sup>32</sup>. For image quantification (R2D2, DII-Venus, mDII-Venus, PIN2-GFP fluorescence intensity measurements), maximum intensity projections of confocal pictures were used. Images were handled and analysed with Fiji (v1.52) and Adobe Photoshop (Adobe Creative Cloud).

# **PIN2-DENDRA photoconversion and FRAP experiments**

PIN2-DENDRA experiments were executed as previously described<sup>71</sup>. Briefly, photoconversion of 5 DAG seedlings expressing *PIN2-Dendra* into its red form induced by illuminating the region of interest with UV light and the depletion of the red and re-appearance of the green signals in ammonium or nitrate transferred *Arabidopsis* roots was followed over time using a vertically oriented LSM700 microscope. Observation of roots initiated 10-20 minutes after transfer and images were recorded every 20 minutes (9 stacks/root/ recording). The experiment was repeated 3 times and each experiment consisted of imaging 6 roots per condition. Image analysis was performed using Fiji (v1.52). Red and green fluorescent signal changes were measured on 10-10 individual cell membranes in the TZ over a period of 6 hours. FRAP experiments were performed as described previously<sup>75</sup>. Briefly, individual membranes of 5 DAG old *PIN2-GFP* expressing *Arabidopsis* roots transferred either to ammonium or nitrate were bleached using the 488nm laser of a Zeiss LSM800 confocal microscope according to its built-in bleaching protocol. Recovery of the PIN2-GFP signal at the bleached areas was followed for 10 minutes and quantification of fluorescence recovery was measured using Fiji (v1.52).

# **PIN2 immunodetection and staining of nuclei**

For PIN2 immunostaining, 5 DAG *Arabidopsis* roots were handled as previously described<sup>76</sup>. Briefly, fixation was performed using 2% PFA (in 1xMTSB) supplemented with 0.1 % TritonX-100, followed by hydrophilisation using MeOH 100 % (65°C, 10 minutes), cell wall digestion using 0.2 % Driselase and 0.15 % Macerozyme in 2 mM MES, pH 5.0 (37°C, 40 minutes), and membrane permeabilisation using 3% NP-40, 10 % DMSO in 1× MTSB (37°C, 20 minutes). Anti-PIN2 (1:100) was used as a primary antibody (37°C, 120 minutes). Alexa Fluor 488 goat anti-rabbit IgG H+L (Thermo Fischer Scientific) was used as secondary antibody (1:800) (37°C, 60 minutes). Finally, samples were mounted in VECTASHIELD® Antifade Mounting Medium with DAPI (4',6-Diamidino-2-Phenylindole, Dihydrochloride). Images were obtained using an LSM800 microscope.

## **Quantification of R2D2, DII-VENUS and mDII-VENUS fluorescence signal in *Arabidopsis* roots**

*R2D2* combines *RPS5A*-driven *DII* (*DII* domain of the *INDOLE-3-ACETIC ACID28* (*IAA28*, *DII*) from *Arabidopsis*) fused to *n3xVenus* and *RPS5A*-driven *mDII* fused to *ntdTomato* on a single transgene<sup>40,46</sup>. *DII-VENUS* is the domain II of *IAA28* fused to the *VENUS* fast maturing YFP and *mDII-VENUS* is the non-degradable form of *DII-VENUS*. The analysis of the fluorescence intensity of either *R2D2*, *DII-VENUS* or *mDII-VENUS* expressing plants grown on ammonium containing and transferred on ammonium and nitrate containing medium was performed on Maximum Intensity Projection of Z-stacks of root tips acquired with a Zeiss LSM 700 inverted laser-scanning microscope as described in<sup>60</sup> with slight modifications. To quantify the fluorescence signal in each cell per selected root tissue (epidermis and cortex) first we positioned a segmented line over the nuclei in the corresponding tissues with the ROI manager tool of the software Fiji (v1.52) (Supplemental Fig 3C). Next, we analyzed the fluorescence plot profiles of the different lines with the peak analyzer function of the software Origin (OriginLab Corporation) to find local maxima along the lines, which represented the fluorescence value of the nuclei in the tissues. In case of *R2D2*, auxin distribution plots were derived by reciprocal mean values of the normalized *n3xVenus*/*ntdTomato* ratio. Relative auxin level data in each cell per tissue were graphed after data interpolation using the Origin built-in algorithm for smoothing.

## **3D SIM and Polar Density Analysis of PIN2-GFP**

Live *Arabidopsis* seedlings, which were incubated on either nitrate or ammonium amended medium for 6-8 hours, were mounted on to coverslips as previously described by Johnson and Vert<sup>77</sup> with the coverslips additionally fixed to the slide with nail polish. Cells in the elongation zone of the root epidermis were imaged using an OMX BLAZE v4 3D SIM (Applied Precision), as described<sup>78</sup>. Briefly, a 60x 1.42 NA Oil Immersion objective and a 100 mW 488 laser was used to make optical sections in the Z dimension, in order to capture the totality of the lateral polar domain of the subject cell. Each Z-section image is based on 15 images generated from 3 different angles and 5 different SIM patterns and reconstructed using SOFTWORX software (Applied Precision).

A maximum projection of the Z-stack was used for analysis. Images were made binary and subjected to watershed segmentation using Fiji<sup>79</sup>. PIN2 spots were then detected using TrackMate<sup>80</sup>. The number of PIN2 spots was calculated in regions of interest (0.8 microns in

width times the height of the cell) at distances sequentially further away from the polar end of the cell using a custom made Matlab script. The raw number of spots in each ROI was then normalised and plotted.

### **Quantification of LUCIFERASE (LUC) activity in *Arabidopsis* roots**

*DR5::LUC* expressing 7 DAG *Arabidopsis* seedlings were transferred to ammonium or nitrate containing agar plates and roots (40 roots per treatment per time point) were collected after 1 and 6 HAT and snap frozen in liquid nitrogen. Frozen root tissue was extracted in Reporter Lysis Buffer (Promega) and LUC activity was measured with the Luciferase Assay Reagent (Promega) in a multiwell plate in a Biotek SynergyH1 platereader.

### **Measurements of basipetal (shootward) auxin transport in *Arabidopsis* roots**

The shootward transport assay of [3H]-IAA in *Arabidopsis* roots was performed according to a previous report<sup>81</sup>, with a few modifications. 7 DAG Col-0 or *eir1-4* seedlings were transferred to ammonium, nitrate or MS (Murashige Skoog Basal Medium) medium with 15 seedlings as one biological replicate, and 3 replicates per treatment. The [3H]-IAA (PerkinElmer, ART-0340) droplets were prepared in MS medium with 1.25% agar and 500 mM [3H]-IAA (1.45 mL in 10 mL) and were carefully placed on the root meristem (at the very end of the roots). After incubation for 6 hours in the dark, the part of the root which was covered by the droplet was cut, the remaining root parts were collected and ground completely in liquid nitrogen and homogenized in 1 mL scintillation solution (PerkinElmer, 6013199). The samples were incubated overnight to allow the radioactivity to evenly diffuse into the whole volume of the scintillation cocktail. Finally the radioactivity was measured with a scintillation counter (Hidex 300XL), with each sample counted for 100 s, 3 times. 3 samples with only the scintillation solution were used as background controls. As an additional background control another batch of samples were prepared the same way as described above except [3H]-IAA containing droplets were placed not on the root meristem but next to the seedlings. Data shown on the figure was calculated against the background.

### **GUS ( $\beta$ -Glucuronidase) staining**

*CycB1::GUS* expression was analyzed in seedling roots 7 DAG, 12 HAT to ammonium or nitrate containing media. Seedlings were incubated for 2 hours in 37°C in staining buffer containing 1mM ferricyanide, 150 mM sodium phosphate buffer (pH 7) and 1mg/ml of X-Gluc dissolved in DMSO. Seedlings were cleared using subsequent incubation at room temperature in a series of ethanol dilutions from 60% to 10% then mounted on slides with 5%ethanol-50%glycerol mounting solution. The pattern of the GUS histochemical staining was analyzed

by an Olympus BX53 microscope and Olympus DP26 digital camera, controlled by cellSense Entry software.

# **RT-qPCR analysis**

Total RNA was extracted from excised 7 DAG roots 1, 6 and 48 HAT to ammonium or nitrate amended plates using RNeasy® Plant Mini kit (QIAGEN) according to the manufacturer's protocol. 1µg of RNA was used to synthesize cDNA using iScript™ cDNA synthesis kit (Bio-Rad). The analysis was carried out on a LightCycler 480 II (SW1.5.1 Version; Roche Diagnostics) with the SYBR Green I Master kit (Roche Diagnostics) according to the manufacturer's instructions. All PCR reactions were carried out with biological and technical triplicates. Expression levels of target genes were quantified by specific primers that were designed using Quant Prime<sup>82</sup>, and validated by performing primer efficiency for each primers pair. The levels of expression of each gene were first measured relative to *AT4G05320* (*UBQ10*) and then to respective mock treatment.

Gene	Transcript Identifier	Primer FW	Primer REV
<i>AT4G05320</i>	<i>UBQ10</i>	<i>CACACTCCACTTGGTCTTGC</i>	<i>TGGTCTTTCCGGTGAGAGTCTTCA</i>
<i>PIN2</i>	<i>AT5G57090.1</i>	<i>TCACGACAACCTCGCTACTAAAGC</i>	<i>TGCCCATGTAAGGTGACTTTCCC</i>
<i>ANR1</i>	<i>AT2G14210.1</i>	<i>AAGAGGAGCAGCATCAACTTCTG</i>	<i>TCCTCTCCCCTAGTTTCCTGTG</i>

# **Reproducibility and statistics**

The number of independent repetitions of experiments, as well as exact sample sizes, is described in the figure legends. Statistical analysis (t-test and ANOVA) were performed using the software Origin (v2018). Statistical significance was tested as described in the figure legends.

For the regression analysis in supplementary document 1, Col-0 cell length measurements were analyzed together with associated categorical variables represented by plant sample of origin (n=18), tissue (n=2, i.e. epidermis and cortex), cell position (n=20) and treatment (n=2, i.e. NO<sub>3</sub><sup>-</sup> and NH<sub>4</sub><sup>+</sup>). The importance of the variables was initially assessed via Random Forest analysis in R (v 1.2.5033). A machine learning training was conducted with the caret R package<sup>83</sup> for tuning the Random Forest and the best mtry parameter was selected according to Root Mean Square Error (RMSE) and R-squared (R<sup>2</sup>) measures in R. Data distribution, skewness and kurtosis were checked with the fitdistrplus R package<sup>84</sup> and Gamma distribution

was chosen for setting up a regression analysis based on generalized linear models (GLMs). Besides the main effects of the variables, several models were virtually possible when the interactions between some or all the variables were considered. First, a simple model including only main effects was generated and residual vs. fitted values evaluated prior to analysis of deviance. Second, a model including main effects and all possible interactions between variables was built. The analysis of the interactions of the fit model was carried out with the *phia* R package<sup>85</sup>, showing a possible but not strong interaction between tissue and treatment factors. This insight was used to generate a third model. The performance of the second and third model was then compared by repeated k-fold cross-validation with the *caret* R package and the second model was selected according to RMSE and R<sup>2</sup> measures. After analysis of deviance, post hoc pairwise comparisons were conducted with estimated marginal means (EMMs) using the *emmeans* R package<sup>86</sup> (Supplemental Document 1a-b). A recursive partitioning analysis was performed and a decision tree was generated with the *partykit* R package<sup>87</sup> to confirm the results showed by regression analysis and to visualize the role of different variables on cell length distribution (Supplemental Document 1c).

## **Computational methods**

### ***Visualization of model predictions***

The computer simulation representing the dynamic auxin flow through the root tissues was created using the version of VV (Vertex-Vertex) programming language and in the L-system-based modeling software L-studio<sup>88</sup>. The model simulates a cross-section of the plant root focusing on the cortical and epidermal tissues. Plant cells are visualized as four-sided polygons representing the cell walls. For the sake of simplicity, cell membranes and the extracellular space shared by adjacent cells are not rendered. Only the first ~20 cells (counting from the QC) are visualized, mirroring the available experimental measurements. Meristematic and elongating cells are distinguished with different cell wall coloring; blue for meristem and yellow for elongation zone, respectively. Auxin is represented as filled green circles inside each cell, the radius of the circle proportional to the size of the cell indicates the amount of auxin present in that cell. PIN2 protein localization on the PM is represented as red dots close to the cell walls; PIN2 can be apical (shootward), basal (rootward) or lateral (outer). Despite being taken into account for mathematical calculations, cytoplasmic accumulation of PIN2 is not shown in the model visualizations. Our model enables dynamic simulation of root growth, elongation and auxin flow through the root apex. Individual cells grow, elongate and consequently divide. Auxin is pumped across cell walls through the ATP-dependent action of

PIN2 proteins on the cell membrane. Auxin that reaches the outer limit of the tissues is simply removed from the system. PIN2 is expressed, trafficked and degraded according to the model rules described in the following sections.

### ***Mathematical model description***

The model assumes that the epidermis contributes to an active passage auxin into deeper tissues. Two main sources of auxin into the epidermis were considered:

- 1) The cell that is closest to the QC, which is known to be a main source of auxin production<sup>89</sup>.
- 2) The lateral root cap, which due to its structural conformation force the influx of auxin into the initial cells of the epidermis<sup>90</sup>.

The ordinary differential equation describing auxin dynamic in a single cell  $i$  is:

$$\frac{dA_i}{dt} = (s_1 \cdot i < z + s_2 \cdot i \geq z) + \sum_{j=1}^n k_a (A_j PIN_j - A_i PIN_i) - d_a A_i$$

Where  $s_1$  and  $s_2$  denote the two auxin sources into the epidermis), while  $z$  indicates the cell location of the LRC-derived auxin influx (cell number 20 from the QC).  $k_a$  represents the rate of active auxin transport between cells via PIN2. The exchange of auxin occurs for each cell  $j$  connected to cell  $i$ . General processes of auxin degradation like conjugation and oxidation are summarized by a single degradation rate,  $d_a$ .

PIN2 is the only auxin efflux carries considered in this model. High auxin concentrations lead to an increased degradation of PIN proteins<sup>48,91</sup>. We modeled the effect of auxin on cytoplasmic PIN2 inside cell  $i$  by approximating functional forms, in what follow:

$$\frac{dPIN_{ci}}{dt} = m_p - d_p PIN_{ci} \cdot \left( 1 + \frac{A_i}{q_p} \right)$$

The expression parameter  $m_p$  indicates the basal rate of PIN2 protein synthesis. PIN2 degradation is modeled over a constant rate of degradation,  $d_p$ , which increases linearly according to auxin levels by  $q_p$ .

PIN2 trafficking to the apical/basal membranes is modeled as follows:

$$\frac{dPIN_{mi}}{dt} = PIN_{ci} (1 - l_n) \left( (tr_n + tr_{wn}) \cdot (1 - tr_n + tr_{wn}) \right) \cdot Logistic (tr_a A_i + tr_i i)$$

The amount of PIN2 on the membrane  $m$  of cell  $i$  is regulated by the basal trafficking rates on  $\text{NO}_3^-$  ( $tr_n$ ) or  $\text{NH}_4^+$  ( $tr_{wn}$ ), which in turn is allowed to saturate to zero or to the maximum rate depending on the level of auxin and the distance from the QC, according to logistic coefficients  $tr_a$  and  $tr_i$ , respectively.  $l_n$  represents the percentage of PIN2 that is redirected to the lateral membranes, depending on nitrate levels. In this model, nitrate level is represented as a binary variable:  $\text{NO}_3^-$  for nitrate supplement and 0 for  $\text{NH}_4^+$  supplement.

Cell division is regulated through a hypothetical division factor as proposed in a previous study<sup>92</sup>. The concentration of division factor in a single cell  $i$  is described as:

$$\frac{dDIV_i}{dt} = k_{v0} \cdot \frac{\left(k_{v1} \cdot \frac{A_i}{\max A}\right) + \left(\frac{len_i}{\max L}\right)}{1 + e^{(i \cdot t_v)}} - DIV_i \cdot k_{v2} \frac{1 + \left(\frac{A_i}{k_{v3}}\right)^{h_1}}{1 + \left(\frac{A_i}{k_{v4}}\right)^{h_2}}$$

Where  $k_{v0}$  denotes the maximal synthesis rate of division factor;  $len_i$  and  $\max L$  the length of cell  $i$  and the maximum cell length achievable, respectively;  $t_v$  is the tolerance factor restricting the location in the meristem where division takes place;  $k_{v1}$  is the level of auxin-dependent division factor activation. The right part of the formula describes the hypothesized process of division factor degradation, where  $k_{v2}$  is the degradation rate of the division factor;  $k_{v3}$  and  $k_{v4}$  are the level of auxin-dependent division factor activation and saturation, respectively;  $h_1$  and  $h_2$  are hill's coefficient.

Cell growth is an auxin-dependent mechanism and cell entrance in the elongation phase is triggered by an auxin concentration threshold. Both in the meristem and the elongation zone cell growth is defined as follow:

$$\frac{dL_i}{dt} = k_l \cdot \frac{A_i}{A_i + 1} L_i \cdot \left(1 - \frac{len_i}{m_l}\right)$$

Where  $k_l$  indicates the cell elongation rate (depending whether the cell in the meristem or in the elongation zone),  $len_i$  the cell length, and  $m_l$  the maximum length the cell can achieve (depending whether the cell in the meristem or in the elongation zone).

### ***Statistical inference and parameters estimation***

Data analysis and plotting was performed using the R language environment for statistical computing<sup>93</sup> and the plotting package ggplot<sup>94</sup>. Parameters estimation of the previously described models was carried out with the RStan<sup>95</sup> and brms<sup>96</sup> packages, which implement a modified version of Hamiltonian Monte Carlo sampling algorithm to approximate the parameters posterior distribution. Model comparison was performed using the loo package<sup>97</sup> to carry out Pareto smoothed importance-sampling leave-one-out cross-validation (PSIS-LOO) for posterior predictive performance estimation.

### ***Auxin source implementation and testing***

To test auxin source impact on the model predictions we considered four possible scenarios (Supplementary Fig. 10f):

- 1) Model A: A naive model assuming a uniform source of auxin along the epidermis (uniform source)
- 2) Model B: The current model that consider two separate sources from the QC and the LRC (LRC source)
- 3) Model C: A highly complex model that assume input source modeled as a versatile spline (spline source)
- 4) Model D: A more complex but less realistic model allowing for different input of auxin for each epidermis cell (multiple point source)

To identify the best model, we tested Models A-D against experimental measurements and generate the information criteria based on the expected log probability density (Supplementary Fig. 10f). A lowest information criterion was found for Model B as indicated the posterior predictive performance, thereby Model B was used for the further study. We decided to exclude the existence of a significant influx of auxin into the cortical cells; this was backed by previous researches which suggested that at high auxin levels endodermal cells have the tendency to lateralize toward the internal tissues and not toward the cortex<sup>98</sup>.

### ***Parameters values used in the model***

Parameters values used in the model are listed below with their estimated mean and lower/upper 95% credible intervals.

Parameter	Mean	l-95% CI	u-95% CI	Reference (when not estimated from data)
$d_a / k_a$	<b>0.018</b>	<b>0.018</b>	<b>0.018</b>	<sup>92</sup>
$s_1$	<b>8.36</b>	<b>0.44</b>	<b>21.54</b>	-
