18 Abstract

19 Establishing laws of plant and ecosystems functioning has been an overarching objective of functional and evolutionary ecology. However, most theories neglect the role of human 20 21 activities in creating novel ecosystems characterized by species assemblages and environmental factors not observed in natural systems. We argue that agricultural weeds, as 22 an emblematic case of such an 'ecological novelty', constitute an original and underutilised 23 model for challenging current concepts in ecology and evolution. We highlight key aspects of 24 25 weed ecology and evolutionary biology that can help to test and recast ecological and evolutionary laws in a changing world. We invite ecologists to seize weeds as a model system 26 27 to improve our understanding of short-term and long-term dynamics of ecological systems in the Anthropocene. 28

29

30 Novelty as a challenge

31 Ecologists and evolutionary biologists have always sought repeated patterns that reveal 32 universal laws of biological function and diversification. Several general theories have been proposed to define ecological and evolutionary processes explaining diversity within and 33 across levels of organization, and across temporal and spatial scales. However, these theories 34 35 are mostly inspired from natural or semi-natural ecosystems, and theoretical models are developed under idealized conditions such as population equilibrium or non-limiting resource 36 37 conditions for plant growth. These theories largely neglect the role of human activities in creating novel ecosystems with original species assemblages and environmental factors. Such 38 'ecological novelties' represent new frontiers of knowledge and create opportunities to 39 challenge widely accepted theories [1], which, in line with Popper's view of science, is a key 40 aspect of the development of theory. 41

The emergence of agriculture during the Neolithic period is perhaps the most widespread 42 43 example of a driver of novel ecosystems. It has created new habitats for numerous plant species [2] (so-called agricultural weeds) which now cover more than 40% of the terrestrial 44 surface [3]. At the scale of the cropped field, weed communities represent melting pots of 45 plant species with various biogeographic and ecological backgrounds and whose local 46 assembly results as much from the movement of crops and civilisations as ecological rules 47 (Box 1). In addition, agricultural practices result in environmental conditions that are unique 48 from conditions in non-cultivated habitats, notably in term of disturbances and resource 49 gradients (Box 2). Mechanical and chemical weeding also represent highly specific and strong 50 51 selection pressures on weed communities [4]. New species combinations and environmental factors in cultivated fields can, therefore, lead to new forms of ecological and evolutionary 52 dynamics that are difficult to capture using well-established theories. 53

54 In this review, we argue that weeds in cropped fields provide a valuable but under-utilised model for challenging conceptual foundation stones in both ecology and evolution in the 55 context of the current era that is characterised by rapid, human mediated change [5]. We 56 discuss how our understanding of short-term and long-term diversification and dynamics of 57 ecological systems should benefit from the study of weeds. In turn, better knowledge of weed 58 59 ecology and evolutionary biology should help explain and predict their dynamics in cultivated fields, which will be necessary to develop innovative weed management schemes 60 that consider both services (e.g. pollination; [6]; [7]) and disservices (e.g. yield loss; [8] [9]) 61 provided by weeds [10]. 62

63 Ecological outliers: why and how can weeds challenge functional ecology

Functional ecology has long been searching for repeated patterns in the phenotypic diversity
of life [11–14]. These patterns reflect the existence of common physiological and biophysical
constraints that structure the 'phenotypic space' of organisms and govern their ability to adapt

to novel environments [13,15]. They are at the basis of major theories in functional ecology 67 68 and macroecology [12,16,17]. For instance, in plants, the leaf economics spectrum describes leaf covariation of physiological and morphological traits that emerge from evolutionary 69 trade-offs between resource acquisition and resource conservation strategies [18]. Most plant 70 species seem to fall along this physiological trade-off [17]. However, these phenotypic 71 72 patterns mostly rely on correlative approaches and, as such, a comprehensive falsification 73 framework is lacking for most of them [19]. Testing the robustness of these laws would allow the validation, or not, of the existence of universal ecological, evolutionary, physiological and 74 biophysical constraints for all taxa on Earth [20,21]. 75

76 Agricultural weeds appear as good candidates to test whether organisms can overcome the constraints and tradeoffs that determine these patterns, and consequently whether (natural or 77 artificial) selection can act against them [15,22]. Recent comparative analyses using taxa 78 spanning continental and global scales show that weeds are located at the margins of the 79 functional space defined by national and global floras [23,24]. Such a position makes them 80 81 potential 'functional outliers', i.e. species functionally distinct from the rest of the global pool of species [25]. In addition, weed species are expected to have greater phenotypic plasticity 82 than non-weeds [26,27], particularly for traits related to reproduction - allowing life cycle 83 84 completion in variable conditions [28–30]. Being at the margins of the plant functional space and having high level of phenotypic plasticity are two key ingredients for weeds to eventually 85 overcome eco-physiological and biophysical constraints that are assumed to limit the 86 diversification of life (Fig. 1A). 87

The possibility of original trait combinations in weeds reflects the unique environmental conditions that characterize the cultivated fields. For instance, enclosed fields and the use of pesticides remove top-down regulation of plant communities by invertebrate and vertebrate herbivores in cropped fields. The removal of natural herbivory in cropped fields can therefore

change the underlying constraints that determine the leaf economics spectrum (resource 92 acquisition vs. conservation;[18]). Moreover, the original combination of disturbance and 93 resource levels in agricultural fields (Box 2) might have selected for weed ecological 94 95 strategies that differ from the ones observed in natural ecosystems. According to the C-S-R model, the combination of disturbance and resource gradients shape three primary plant 96 ecological strategies that explain the diversity of the whole flora [31]. A high level of resource 97 availability and a low level of disturbance select for species that display a combination of 98 traits that make them good competitors ('Competitor species', C). 'Stress-tolerant' (S) species 99 occur where both resource availability and disturbance levels are low while 'Ruderal' (R) 100 101 species are adapted to habitats where both resource availability and the levels of disturbance are high. Finally, no trait combination allows species to persist in environments where 102 disturbance level is high and resources availability is low [31]. Intriguingly, the CSR scheme 103 104 has been built on habitat characteristics where species are found, not on the levels of resources and disturbance actually perceived by the organisms. This approach may be limited 105 106 in seeking to understand the functional ecology of agricultural weeds that occur in habitats 107 characterized by high levels of resources and disturbance but also experience severe resource depletion, notably in light, the latter being largely preempted by the crop species that is 108 artificially dominant (Box 2). Agricultural weeds thus face repetitive disturbances in the 109 context of strongly imbalanced resource ratios [32]. This extreme situation is not considered 110 in the traditional CSR model where the ability of species to capture above and below ground 111 resources is assumed to co-vary along a stress tolerant - competitive gradient (Fig. 2B). The 112 exceptional combination of disturbances and the imbalance above and belowground resources 113 available for weeds in agricultural fields thus questions the CSR model developed from 114 115 observations in natural ecosystems. A greater consideration of the effect of imbalance

resource availability on the evolution of plant ecological strategies is required to betterunderstand the success of weeds in cultivated habitats.

Functional ecology approaches to studying weeds are at their infancy. While the ruderal 118 119 strategy has traditionally been related to weeds, empirical evidence shows that a wider range of ecological strategies also exist in weeds [24]. Particularly, weeds species differ between 120 those that compete with the crop and those that avoid it as well as between species that resist 121 122 or avoid disturbances [33,34]. These results suggest that the same environmental constraints may select for a variety of ecological strategies that can co-exist in the same field. Improving 123 the characterization of the whole weed biota through the lens of functional traits will allow the 124 125 species able to establish and persist in arable habitats to be identified (so-called 'regional pool' in community ecology). This will inform the profiling of future weed communities and 126 the assessment of the physiological and biophysical constraints that regulate weed success and 127 their potential to adapt. 128

129 2. Challenging community assembly rules

Weed science has largely focused on understanding the biology and control of individual 130 weeds infesting cropland. However, plant species do not act independently but are imbedded 131 132 in complex interaction networks, both within and between local communities. This evidence has motivated the seminal article of Booth & Swanton [35] that calls for a shift from species 133 to community level studies in weed science. Yet, despite an increasingly number of studies 134 addressing weed community assembly, the rules that govern weed community dynamics 135 remain far from clear, making predictions of the impact of any change in farming practices 136 difficult (e.g., refs. [36-41]). Here, we argue that this may result from the fact that weed 137 communities display particular dynamics that cannot be fully capture by classical ecological 138 theories. 139

Whether the assembly of ecological communities follow general rules is a fundamental but 140 141 still unresolved question in community ecology [42]. One of the most challenging issues is to understand and model the combined influences of stochastic, neutral (i.e. independent from 142 143 biological differences) and niche-based (i.e. biotic interactions and environmental filtering) processes on community assembly [43-45]. According to the stress gradient hypothesis, 144 competition should govern community assembly in productive habitats while harsh 145 environmental conditions should filter stress-tolerant species [45]. By contrast, community 146 147 assembly can be neutral where both competition and environmental stress are weak, for example after a disturbance that strengthens the influence of stochastic species recruitment 148 [45]. However, weed communities occupy habitats where competition, environmental 149 filtering and stochastic dynamics are all extremely strong (Box 2). Intense competition arises 150 from a pre-emption of space and light by the crop, which strongly reduces weed biomass 151 152 [46,47]. Abiotic constraints are caused by agricultural practices such as chemical weeding and soil disturbances (i.e. tillage and mechanical weeding), which filter out species according to 153 154 their sensitivity to herbicides and to their phenology, respectively [48,49]. These recurring disturbances further maintain the farmed ecosystem in early stages of secondary succession 155 (i.e. dominance of annuals; [50]), where stochastic colonization-extinction dynamics also play 156 an important role ([40,41,51,52]). These dynamics might however shift in no-till systems 157 158 where the abandonment of ploughing favour more perennial weed species [7,53]. Weed communities thus represent a combination of transient species that rely on repeated 159 colonisation from field edges and resident species that are adapted to the habitat filters in the 160 field [52]. Because of the unique combination of niche-based and neutral processes in 161 cultivated fields, weed communities are particularly valuable for investigating how complex 162 163 assembly dynamics govern species persistence and coexistence across spatial scales.

Another critical issue in the Anthropocene is to predict the responses of communities to 164 anthropogenic environmental changes [54,55]. Spatial variation contributes to species 165 coexistence via the spatial storage effect [56] that allows less competitive species to migrate 166 167 and persist in communities (source-sink dynamics, [57]). By contrast, temporal variation can modify the competitive hierarchy between species, allowing species to coexist over the long-168 term (i.e. temporal storage effect, [56]). However, ecological theories implicitly assume 169 stationary regimes of environmental variation so that some coexistence equilibrium is reached 170 171 at a given time (reviewed in [55]). In the case of agricultural weeds, this fundamental assumption is violated by abrupt changes imposed by changing human activities, which 172 prevents the system reaching any long-term stability. Over decadal time scales, the 173 development of new agricultural practices and the abandonment of ancient ones has strongly 174 affected the dynamics of weed populations, as some formerly rare weeds become more 175 176 successful and vice et versa [49,58]. Similarly, the introduction of new cultivated species within a region (e.g. rapeseed, sugar beet, sunflower in France) creates unprecedented 177 178 environmental conditions that can radically change the composition of weed communities in just a few years [59]. From year to year, the sequential cultivation of different crop species 179 within a field also causes large fluctuations of disturbance regimes and competitive 180 181 interactions [60]. Such non-stationary environmental constraints should theoretically drive deviations from community equilibrium within an environment at a given time by favouring 182 transient and delayed species responses (lag response hypothesis; [55,61]). This has been 183 verified empirically with agricultural weeds where temporal dispersal from the dormant 184 seedbank allows the presence of weed species that reproduced successfully under previous, 185 more suitable conditions (i.e. temporal source-sink dynamics, [38,41,62]). The ability of 186 187 weeds to colonise novel cropping environments over short time scales will also be related to spatial dynamics of introductions of seed in crops and on machinery or dispersal from 188

surrounding habitats, involving stochastic processes and landscape composition [63,64].
Weeds thus represent an exemplary case to elaborate a "non-equilibrium" community
assembly theory, a theory that is urgently needed to better understand and anticipate plant
community responses to the ongoing global changes [65].

3-Weeds: evolutionary roadrunners?

Although scientists long assumed that evolution proceeds slowly, an increasing number of 194 195 examples of rapid evolution have been documented in wild plant species (e.g. [66,67]). 196 Evidence of rapid phenotypic and molecular evolution challenge the classical view of the 197 standard model of population genetics [68]. Furthermore, because ecological and evolutionary time scales overlap, ecological and evolutionary process are now known to interact and we 198 need to understand how evolutionary process can affect population growth rates and 199 200 ecological dynamics [69]. A better understanding of rapid evolution and eco-evolutionary dynamics is particularly crucial given that these phenomena may become increasingly 201 frequent in the Anthropocene [70] due to the dramatic acceleration of human driven 202 203 ecological changes ("the Great Acceleration," [5]).

Rapid evolution is particularly frequent in agricultural fields where farming practices have 204 caused intense but unintended selective pressures on weeds since the Neolithic. The 205 206 contribution of the genetic attributes of weeds and their evolutionary dynamics (in term of mating systems, phenotypic plasticity, and many other adaptive traits) to their capacity for 207 208 rapid evolution in a new human-made environment have been repeatedly pointed out [2,4,29,71–73]. The evolution of herbicide resistance is probably the most emblematic and 209 well-documented case of rapid evolution in plants (reviewed in [74]). Beyond herbicide 210 resistance, rapid evolution can also affect weed demography by controlling weed-crop or and 211 212 weed-pathogens interactions. For example, Guo et al. [75] demonstrated the rapid evolution of allelopathy and pathogen resistance in the barnyard grass (Echinochloa crus-galli) in response 213

to co-cultivation with rice and to infection by pathogenic Pyricularia oryzae, respectively. In 214 215 addition, many weed species rapidly evolve traits that mimic the crops to survive the selective constraints historically imposed by the farmers (Vavilovian mimicry, [76,77]). For instance, 216 217 there is evidence that populations of Agrostemma githago have adapted to mimic the size and shape of crop seed to avoid being removed during seed cleaning ([78]). This species is also 218 virtually indistinguishable from wheat during the vegetative stage (Figure 2), which also 219 220 probably allows it to escape from manual weeding in traditional farming systems. Another 221 example is the evolution of the crop mimicry syndrome in Camelina alyssum (Mill.) Thell. that has led to the weed reducing its phenotypic plasticity ([28]). If the evolution of vegetative 222 or seed traits has been driven by crop mimicry, by contrast floral traits may have 223 differentiated from crops due to divergent selection. For example, Agrostema githago 224 225 produces flowers that are clearly visible among wheat plants; presumably, to attract 226 pollinators and ensure reproduction at low plant densities in self-pollinating crop stands 227 (Figure 2). Thomann et al. [79] also reported the evolution of increased capitula size in the 228 cornflower (Cyanus segetum), in parallel with pollinator decline in 1990's agrosystems in 229 northern Europe. However, the generalization of contrasted selection pressures on vegetative and floral traits in weeds, as well as the mechanisms of convergent and divergent evolution, 230 231 remain an open question.

The realization that evolution can occur on short time suggests the existence of reciprocal interactions between ecological and evolutionary dynamics [69]. Although a growing number of studies show that rapid trait evolution can drive ecological dynamics on contemporary time scales, there are few empirical evidence of feedbacks from these altered ecological interactions on the evolutionary responses of plant communities [80]. Recently, Baucom [74] argue that weed communities exposed to herbicides provide an attractive system to study such eco-evolutionary feedbacks. Indeed, the emergence of resistance boosts the demography of

resistant populations in agrosystems that can in turn affect pollinator communities and disease 239 240 prevalence. The resulting changes in biotic interactions between weeds and other trophic levels can in turn promote the evolution of new weed species traits (see Fig. 1 in [74]). Here, 241 242 an important and still unresolved question is to identify functional traits that can drive rapid evolution and eco-evolutionary dynamics. Plant genome size (GS) might be such a trait as it 243 244 simultaneously controls evolutionary rates and several important plant functional traits such 245 as plant relative growth rate and generation time [81,82]. Intriguingly, Bennett [77] reported 246 that GS was smaller in weeds than in non-weeds although polyploidy was more common in This is surprising given that plant GS positively correlates with the amount of 247 weeds. 248 repetitive DNA that result from hybridization and/or polyploidy (at least soon after such polyploidization events occur; [78]). Antagonistic forces may therefore drive plant GS size 249 250 and ploidy level in agricultural weeds.

251 Finally, archeological findings provide both a chronology of agricultural innovations and a parallel record of associated weed floras from archaeological remains (e.g. [85,86]), making 252 253 agricultural weeds remarkable models to understand the genetic basis of rapid evolution as well as the evolutionary trajectories of complex traits in natural populations. The progress in 254 ancient DNA sequencing techniques makes it possible to scan whole genomes of weed 255 256 historical samples to detect candidate genes under selection. On a shorter time scale, 257 resurrection ecology [87] and museum specimen analysis [88] can also be a relevant methodologies to investigate weed trait evolution and its genetic and epigenetic underpinning 258 over hundreds to a few dozens of generations. Weeds are particularly useful for this approach 259 260 since most of these species are annuals producing numerous seeds that persist in soil seedbank for decades [89]. Recent resurrection experiments on weed species have for example revealed 261 262 rapid evolution on herbicide and drought resistance, pathogen susceptibility, phenology, floral traits and pollination biology and adaptive plasticity [79,87,90]. Coupling resurrection 263

ecology with genome wide association mapping will be a key approach to understand the genetic basis of rapid evolution of multiple and complex traits in response to documented selective pressures (e.g. [91]).

267 Concluding remarks

Understanding the impacts of human activities on ecological and evolutionary dynamics will 268 require revisiting ecological theories initially developed for natural ecosystems (see also 269 270 oustanding questions). Pivotal to this is the integration of reciprocal interactions between human activities and ecological and evolutionary processes. Because weed evolutionary 271 272 history and ecological dynamics are linked intrinsically to human activities, these species 273 have great potential to become a valuable model in ecology and evolution. Yet, weeds are absent from most ongoing efforts of global biodiversity and trait databases, or at least their 274 peculiarities are not recognized (due to e.g., lack of vegetation plot data in cropping systems, 275 lack of data on intraspecific trait variation). We urge (numerical) ecologists not to discard the 276 amazing source of information coming from weed species and their associated habitats. Field 277 278 ecologists might have also overlooked widespread cultivated habitats compared to rare and emblematic ones. However, studying plant community assembly using weed communities is 279 an attractive prospect given that assembly processes can be more easily identified, deciphered 280 281 and quantified. Finally, weeds, by their short life cycle and relatively simple genome, appear as preferential experimental models for ecology and evolution. Let ecologists and 282 evolutionists seize the weeds! 283

496 Box 1. How to become an agricultural weed?

497 Three roads can lead a plant species to become a weed: wild species invading fields, crop-498 wild hybridization and crop de-domestication [72,92].

First, crop domestication during the Neolithic has resulted in the construction of a new 499 human-made ecological niche, the agricultural fields in different part of the world [93]. At 500 this moment, and in each center of plant domestication, numerous local pre-adapted plants 501 were able to colonize cultivated fields [94]. These proto-weeds probably locally evolved 502 according to the man-made selective pressures (the first agricultural practices) during 503 504 millennia, as plant cultivation started long before crop domestication, at least in the Levant 505 [95]. Some of these species still exist in both cultivated and non-cultivated habitat (*i.e.* apophytes), while others such as Lolium temulentum, Bromus secalinus, Agrostemma githago 506 or Vaccaria hispanica, are only known in agricultural habitats (i.e. anecophytes). 507

Second, the expansion phase of agriculture has then carried out secondary contact among previously isolated populations or species, both domesticated and wild, generating admixture or hybridization [96,97]. Hybridization has triggered the emergence and diversification of many emblematic weed species such as *Capsella bursa-pastoris* [98], *Veronica persica* [99], or *Chenopodium album* [100]. Moreover, during the expansion phase, pre-adapted plant species from the newly cultivated areas could enter in the field adding new species [2].

17

Finally, some contemporary weed species are the result of de-domestication from cultivated ancestors (e.g. weedy rice, *Oryza sp.* [101]; weedy radish, *Raphanus sp.* [102]). By definition, these feral species are highly adapted to their early agricultural practices. This can explain why these weed species are notoriously ones of the most problematic weeds in contemporary farming [102].

519 These various processes make modern weed communities a unique assemblage of species520 with various biogeographic origins and evolutionary histories.

521

522 Box 2. Environmental gradients in cultivated fields.

Environmental conditions in cultivated fields refer to both local pedo-climatic conditions and 523 farming practices. Farming practices such as tillage and weeding operation correspond to 524 major disturbance events in arable fields [60]. Crop phenology (e.g. sowing date, harvest date) 525 notably determines the timing of disturbance during while herbicide intensity and tillage 526 527 depth dictate the intensity of disturbance. In addition, the soils of cultivated habitat are extremely rich in resources as fertilization and irrigation provide large amounts of nutrient 528 and water. Although fertilization and irrigation mostly benefit the crop species, the amount of 529 530 nutrient and water supplies are such that they remain largely non-limiting for weeds [103]. By contrast, the amount of space and light that are available for weeds are strongly limited by the 531 532 presence of the crop species that produce most of the standing biomass in agricultural fields. The amount of aboveground resources pre-empted by the crop varies according to crop 533 534 height, lateral spread and sowing density [104].

The rapid monopolization of space and light by one species in a regularly disturbed habitat is specific to cultivated fields [4]. In non-cultivated ecosystems, disturbance releases resources by destroying biomass, so that regularly disturbed habitat generally show high level of

18

resources availability [105]. By contrast, in cultivated fields, crop characteristics more than disturbances dictates the amount of available resources for weeds so that the positive covariance between disturbance and resource gradients do no longer exist. Finally, the succession of different crop species and associated farming practices within a field (i.e. crop sequences) causes major year-to-year changes in both disturbances and resources availability [60].

544 Figure 1. Whether and how weed species can break functional ecology rules: theoretical expectations. (A) Functional ecology has highlighted cross-taxa trait-trait relationships that 545 mirror physiological and biophysiological constraints at the origin of the diversification of 546 547 life. For instance, the leaf economics spectrum describes a trade-off between photosynthetic rate (trait Y) and leaf lifespan (trait X) among many plant species [16]. Each gray dot 548 represents a given species. Weed species have been characterized as functional outliers 549 because they were located at the margins of the multi-trait space (so-called functional space) 550 551 in recent cross-taxa comparative studies. In addition, weed species are expected to display 552 high phenotypic plasticity ability, which can help them to overcome the envelope of 553 constraints delineated by functional ecological laws. (B) The CSR theory delineates a triangle 554 of tenable strategies of species based on the characteristics of the habitat where they live, 555 namely resources and disturbances. However, when decoupling resources into aboveground and belowground resources to account for the levels of resources that are available for weeds, 556 weeds might be considered as functional outliers in this untenable triangle. Indeed, they 557 undergo high disturbance level, high belowground resources but low aboveground resources 558 due to high depletion of light availability by the crop species. Such imbalance between 559 560 belowground and aboveground resources is not considered in the traditional CSR model.

Figure 2. Phenotypic convergence and divergence between wheat and the common corn
cockle (*Agrostemma githago*). Left: At the vegetative stage, the common corn cockle is

- virtually indistinguishable from wheat. Right: By contrast, floral traits strongly diverge. Photo
