Abstract

Because most natural phenomena exhibit dependence at multiple scales like locations of earthquakes or forest fire occurrences, spatio-temporal single-scale point process models are unrealistic in many applications. This motivates us to construct generalizations of classical Gibbs models. In this paper, we extend the Geyer saturation point process model to the spatio-temporal multi-scale framework. The simulation process is carried out through a birth-death Metropolis-Hastings algorithm. In a simulation study, we compare two common methods for statistical inference in Gibbs models: the pseudo-likelihood and logistic likelihood approaches that we tailor to this model. Finally, we illustrate this new model on forest fire occurrences modelling in Southern France.

Keywords: Spatio-temporal Gibbs point processes, Hybridization, Pseudo-likelihood, Logistic likelihood, Forest fires.

1. Introduction

Nowadays point process models are widely used to highlight trends and interactions in the spatial or spatio-temporal distribution of events. Most of them are single-structure in the sense that they exhibit either spatial randomness (e.g.

5 modelled by the Poisson process [33, 34]) or clustering (mostly modelled by Cox
processes [16], in particular log-Gaussian Cox processes [41, 14, 12, 20], Poisson
Cluster processes [44, 13, 21] and Shot-Noise Cox processes [11, 42, 40]) or inhibi-
tion (modelled by Strauss processes [60, 17], Matérn hard core processes [39, 24]
and determinantal point processes [38, 35]). However, lot of phenomena present
10 interactions at different scales what motivate statisticians to develop new mod-
els, mainly spatial models in ecology [36, 64, 49], epidemiology [30] or seismol-
ogy [58, 59], but very few spatio-temporal models in environment [23] or epi-
demiology [29] as lately reviewed in [51]. Multi-scale models are mostly based on
Gibbs models (see [19] for a recent review on Gibbs models) as they offer a large
15 class of models which allow any of the above mentioned interaction structure.
Multi-structure models can then be obtained by hybridization [7].

Gibbs point processes are studied by their probability density, defined with
respect to the unit rate Poisson point process. Well-known inhibitive Gibbs
models include the hardcore model (events are forbidden to come too close
20 together) and the Strauss model [60] (pairs of close events are not impossible but
are unlikely to occur). Generalizing the Strauss process, the Geyer saturation
process [26] intends to model both inhibition and clustering. It is able to take
into account the clustering nature of a pattern due to interactions between
points in absence of covariate information [1].

25 [7] defined a new class of multi-scale Gibbs point processes, so-called hybrid
models. The hybridization technique consists in defining the density function
of a multi-scale point process model as the product of several densities of Gibbs
point processes, f_l for $l = 1, \dots, m$, so that $f = cf_1 \times \dots \times f_m$ where c is
a normalization constant. The choice of the normalization constant allows to
30 well define a probability density in the case where the product of densities is
integrable. In particular, [7] introduced the spatial multi-scale Geyer saturation
point process that has then been applied in epidemiology [30] and in seismol-
ogy [58, 59]. [29] extended the hybridization approach to the spatio-temporal
framework and introduced the spatio-temporal multi-scale area-interaction pro-
cess. **New hybrid Gibbs models can also be defined from the hardcore process**
35

[17] and the Strauss process [28] introduced in the spatio-temporal framework, but much more hybrid Gibbs models remain to be developed to better describe spatio-temporal complex phenomena in practice.

Forest fire occurrences present multi-scale structures which are related to spatial or spatio-temporal inhomogeneities of environmental and climate covariates as well as influence of past events. Their complex interaction structure has been modelled by a spatio-temporal log-Gaussian Cox process in [47] and with an inhibitive effect as covariate in [23]. Gibbs point process models have also been considered in the spatial context for modelling wildfires like the area-interaction point process [32, 53, 62, 2, 65] or the Geyer point process [63]. In this paper, we aim to extend the spatial Geyer saturation point process to the spatio-temporal framework replacing the Euclidean balls by spatio-temporal cylindrical neighbourhoods [28]. We also introduce its multi-scale version by extending the hybridization approach [7] to space and time. We then model forest fire occurrences using our spatio-temporal multi-scale Geyer saturation point process. Our data, available from the Prométhée database¹, concern forest fire occurrences in the Bouches-du-Rhône department (South of France) between 2001 and 2015.

The spatio-temporal multi-scale Geyer saturation point process model is introduced in Section 2. In Section 3, we extend the pseudo-likelihood and logistic likelihood approaches for statistical inference of Gibbs models to the spatio-temporal framework. Then in Section 4 we implement the model simulation using a birth-death Metropolis-Hastings algorithm and present a simulation study to compare the performance of the two estimation methods. Finally, in Section 5, we apply our model to forest fire occurrences in Southern France.

2. Spatio-temporal Geyer saturation point process

A spatio-temporal point process can be viewed as a random locally finite subset of a Borel set $W = S \times T \subset \mathbb{R}^2 \times \mathbb{R}$. We consider a complete, separable metric space $(W, d(\cdot, \cdot))$ where $d((u, v), (u', v')) := \max\{\|u - u'\|, |v - v'|\}$ for $(u, v), (u', v') \in W$. For \mathcal{N} the state space of points configurations of W , $\mathbf{x} \in \mathcal{N}$ denotes a point pattern, i.e. $\mathbf{x} = \{(\xi_1, t_1), \dots, (\xi_n, t_n)\}$ where (ξ_i, t_i) describes the location and time, respectively, associated with the i^{th} event.

The cylindrical neighbourhood $C_r^q(u, v)$ centred at $(u, v) \in S \times T$ is defined as

$$C_r^q(u, v) = \{(a, b) \in S \times T : \|u - a\| \leq r, |v - b| \leq q\}, \quad (1)$$

where $r, q > 0$ are spatial and temporal radii, $\|\cdot\|$ denotes the Euclidean distance in \mathbb{R}^2 and $|\cdot|$ denotes the usual distance in \mathbb{R} . Note that $C_r^q(u, v)$ is a cylinder with centre (u, v) , radius r , and height $2q$ that represents a natural neighbourhood for extending spatial Gibbs models to the spatio-temporal context [28].

The Papangelou conditional intensity [48] of a spatio-temporal point process on W with density f is defined by

$$\lambda((u, v)|\mathbf{x}) = \frac{f(\mathbf{x} \cup (u, v))}{f(\mathbf{x} \setminus (u, v))}, \quad (2)$$

with $a/0 := 0$ for $a \geq 0$ and $(u, v) \in W$ ([17]). Hence, we have $\lambda((u, v)|\mathbf{x}) = \frac{f(\mathbf{x} \cup (u, v))}{f(\mathbf{x})}$ if $(u, v) \notin \mathbf{x}$ and $\lambda((u, v)|\mathbf{x}) = \frac{f(\mathbf{x})}{f(\mathbf{x} \setminus (u, v))}$ if $(u, v) \in \mathbf{x}$.

[28] introduced a spatio-temporal Strauss process with conditional intensity for $(u, v) \notin \mathbf{x}$

$$\lambda((u, v)|\mathbf{x}) = \lambda \gamma^{\tilde{n}(C_r^q(u, v); \mathbf{x})}, \quad (3)$$

where $\tilde{n}(C_r^q(u, v); \mathbf{x}) = \sum_{(\xi, t) \in \mathbf{x}} \mathbb{1}\{\|u - \xi\| \leq r, |v - t| \leq q\}$ is the number of points of \mathbf{x} lying in $C_r^q(u, v)$.

The density function of Strauss model is not integrable for $\gamma > 1$, it thus does not define a valid probability density and the Strauss process can not be intended for clustering structures. To avoid this issue, [26] consider an upper bound (saturation parameter) for the number of neighboring points that interact and define the (spatial) Geyer saturation point process.

Definition 1. We define the *spatio-temporal Geyer saturation point process* as the point process with density

$$f(\mathbf{x}) = c \prod_{(\xi, t) \in \mathbf{x}} \lambda(\xi, t) \gamma^{\min\{s, n(C_r^q(\xi, t); \mathbf{x})\}}, \quad (4)$$

with respect to a unit rate Poisson process on W , where $c > 0$ is a normalizing constant, λ is a non-negative, measurable and bounded function, $\gamma > 0$ is the interaction parameter, s is the saturation parameter, and $n(C_r^q(\xi, t); \mathbf{x}) = \sum_{(u, v) \in \mathbf{x} \setminus (\xi, t)} \mathbb{1}(|u - \xi| \leq r, |v - t| \leq q)$ is the number of points of \mathbf{x} lying in $C_r^q(\xi, t)$ and different from (ξ, t) .

The function λ describes some spatio-temporal trend in point pattern that can be estimated using covariates. The scalars γ, r, q and s are the parameters of the model. The saturation parameter s is an upper bound of the number of points in the cylinder C_r^q . By using hybridization approach [7, 29], we define a multi-scale version of (4).

Definition 2. We define the *spatio-temporal multi-scale Geyer saturation point process* as the point process with density

$$f(\mathbf{x}) = c \prod_{(\xi, t) \in \mathbf{x}} \lambda(\xi, t) \prod_{j=1}^m \gamma_j^{\min\{s_j, n(C_{r_j}^{q_j}(\xi, t); \mathbf{x})\}}, \quad (5)$$

with respect to a unit rate Poisson process on W , where $\gamma_j > 0$, $j = 1, \dots, m$, are the interaction parameters, and $r_1 < \dots < r_m$, $q_1 < \dots < q_m$ are spatial and temporal interaction ranges.

For any $j \in \{1, \dots, m\}$, the interaction parameters $0 < \gamma_j < 1$ reflect inhibition, while $\gamma_j > 1$ reflect clustering between points at some spatio-temporal scales. When $s_j = 0$ or $\gamma_j = 1$ for all $j \in \{1, \dots, m\}$, the density (5) corresponds to the density of an inhomogeneous Poisson process. Equation (5) indicates that the structure of the process changes with the spatial and temporal distances r_j, q_j . Covariates can be added to the model by assuming that the spatio-temporal trend λ is function of a covariate vector $Z(\xi, t)$, i.e. $\lambda(\xi, t) = \Psi(Z(\xi, t))$.

Lemma 1. The spatio-temporal multi-scale Geyer point process is a Markov point process in the sense of Ripley-Kelly [52] and its density (5) is measurable and integrable for all $\gamma_j, j = 1, \dots, m$ with $m \in \mathbb{N}$.

105 *Proof.* A Geyer model is hereditary, locally and Ruelle stable and hence integrable [26]. [7] showed these properties for hybrids. As in [29], we can show that the spatio-temporal Geyer saturation point process (4) is a Markov point process in Ripley-Kelly's sense at interaction range $2 \max\{r, q\}$ and that the
 110 spatio-temporal multi-scale Geyer saturation process (5) is also a Markov point process in Ripley-Kelly sense at interaction range $\max_{1 \leq j \leq m} \{2 \max\{r_j, q_j\}\} = 2 \max\{r_m, q_m\}$ ([7]). \square

For any $(u, v) \in W$, the Papangelou conditional intensity function of the spatio-temporal multi-scale Geyer saturation process is

$$\begin{aligned} \lambda((u, v) | \mathbf{x}) &= \lambda(u, v) \prod_{j=1}^m \gamma_j^{\min\{s_j, n(C_{r_j}^{q_j}(u, v); \mathbf{x})\}} \\ &\times \prod_{(\xi, t) \in \mathbf{x} \setminus (u, v)} \gamma_j^{\min\{s_j, n(C_{r_j}^{q_j}(\xi, t); \mathbf{x} \cup (u, v))\} - \min\{s_j, n(C_{r_j}^{q_j}(\xi, t); \mathbf{x} \setminus (u, v))\}}, \end{aligned} \quad (6)$$

The Markovian property (Lemma 1) ensures that this conditional intensity only depends on (u, v) and its neighbors in \mathbf{x} . Hence, we can design simulation algorithms for generating realizations of the model, see Section 4.

115 3. Inference

Geyer saturation point process model (4) involves two types of parameters: regular parameters and irregular parameters. A parameter is called *regular* if the log likelihood is a linear function of that parameter, *irregular* otherwise. Regular parameters like trend λ and interaction γ can be estimated using the
 120 pseudo-likelihood method [5] or the logistic likelihood method [3] rather than the maximum likelihood method [45]. **Indeed, they are based on the conditional intensity which is tractable for most Gibbs models and is free from the normalization constant c (whose estimation is computationally very expensive, even**

for a small number of regular parameters). Here we tailor these two methods
 125 to estimate regular parameters of our spatio-temporal model and we compare
 their performance in the next section.

Irregular parameters, like saturation threshold s and distances r and q , are
 difficult to estimate using the maximum likelihood method because the like-
 likelihood function is not differentiable with respect to them. These parameters
 130 can be estimated using the profile pseudo-likelihood approach [5] or predeter-
 mined by the user using some summary statistics, like the pair correlation and
 the auto-correlation functions [29], in order to determine the interaction ranges.
 [6] presented the methods that are used for irregular parameter estimation in
 the spatial framework.

135 In this paper, we combine the advantages of the two previous methodologies.
 By computing some statistics summarizing the range of interactions in space and
 time, we consider a set of feasible irregular parameter values and we choose the
 combination of them providing the best Akaike's Information Criterion (AIC)
 for the fitted model.

140 3.1. Pseudo-likelihood approach

Let $\boldsymbol{\theta}$ be the vector of regular parameters that we aim to estimate. [10]
 defined the pseudo-likelihood for spatial point processes in order to avoid com-
 putational problems with point process likelihoods. One can easily extend it for
 a spatio-temporal point process with conditional intensity $\lambda_{\boldsymbol{\theta}}((u, v)|\mathbf{x})$ over W
 as follows

$$PL(\mathbf{x}; \boldsymbol{\theta}) = \exp \left(- \int_S \int_T \lambda_{\boldsymbol{\theta}}((u, v)|\mathbf{x}) dv du \right) \prod_{(\xi, t) \in \mathbf{x}} \lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x}). \quad (7)$$

The pseudo score is defined by

$$U(\mathbf{x}; \boldsymbol{\theta}) = \frac{\partial}{\partial \boldsymbol{\theta}} \log PL(\mathbf{x}; \boldsymbol{\theta}), \quad (8)$$

that is an unbiased estimating function. The maximum pseudo-likelihood nor-
 mal equations are then given by

$$\frac{\partial}{\partial \boldsymbol{\theta}} \log PL(\mathbf{x}; \boldsymbol{\theta}) = 0, \quad (9)$$

where

$$\log PL(\mathbf{x}; \boldsymbol{\theta}) = \sum_{(\xi, t) \in \mathbf{x}} \log \lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x}) - \int_S \int_T \lambda_{\boldsymbol{\theta}}((u, v) | \mathbf{x}) dv du, \quad (10)$$

and $\lambda_{\boldsymbol{\theta}}(\cdot | \mathbf{x})$ is defined by (6) for hybrid Geyer model (5).

For sake of clarity, we now assume that $\boldsymbol{\theta} = [\log \gamma_1, \dots, \log \gamma_m]^\top$ the logarithm of interaction parameters in model (5). To estimate $\boldsymbol{\theta}$, we use the pseudo-likelihood approach. Equation (6) can be rewritten as $\lambda_{\boldsymbol{\theta}}((u, v) | \mathbf{x}) = \lambda(u, v) \prod_{j=1}^m \exp(\theta_j S_j((u, v), \mathbf{x}))$ where

$$\begin{aligned} S_j((u, v), \mathbf{x}) &= \min\{s_j, n(C_{r_j}^{q_j}(u, v); \mathbf{x})\} \\ &+ \sum_{(\xi, t) \in \mathbf{x} \setminus (u, v)} [\min\{s_j, n(C_{r_j}^{q_j}(\xi, t); \mathbf{x} \cup (u, v))\} \\ &\quad - \min\{s_j, n(C_{r_j}^{q_j}(\xi, t); \mathbf{x} \setminus (u, v))\}], \end{aligned} \quad (11)$$

is a sufficient statistics. Then, for $\mathbf{S}((u, v), \mathbf{x}) = [S_1((u, v), \mathbf{x}), \dots, S_m((u, v), \mathbf{x})]^\top$

$$\log \lambda_{\boldsymbol{\theta}}((u, v) | \mathbf{x}) = \log \lambda(u, v) + \boldsymbol{\theta}^\top \mathbf{S}((u, v), \mathbf{x}) \quad (12)$$

is a linear model in $\boldsymbol{\theta}$ with offset $\log \lambda(u, v)$. Thus, equation (9) gives us the pseudo-likelihood equations

$$\frac{\partial}{\partial \boldsymbol{\theta}} \left[\sum_{(\xi, t) \in \mathbf{x}} [\log \lambda(\xi, t) + \sum_{j=1}^m \theta_j S_j((\xi, t), \mathbf{x})] - \int_S \int_T \lambda(u, v) \prod_{j=1}^m e^{\theta_j S_j((u, v), \mathbf{x})} dv du \right] = 0, \quad (13)$$

For each parameter $\theta_i, i = 1, \dots, m$, the equations (13) can be rewritten

$$\sum_{(\xi, t) \in \mathbf{x}} S_i((\xi, t), \mathbf{x}) = \int_S \int_T \lambda(u, v) S_i((u, v), \mathbf{x}) \prod_{j=1}^m e^{\theta_j S_j((u, v), \mathbf{x})} dv du, \quad (14)$$

The major difficulty is to estimate the integrals on the right hand side of equations (14). The pseudo-likelihood cannot be computed exactly but must be approximated numerically.

145 For a point process model, the approximation of likelihood is converted into a regression model. In the following, we refer to generalized log-linear Poisson

regression approach as approximation of integrals in (14). In the next subsection, we also investigate an alternative, the logistic regression.

[9] developed a numerical quadrature method to approximate maximum likelihood estimation for an inhomogeneous Poisson point process. Berman-Turner method has then been extended to Gibbs point processes by [5], approximating the integral in (10) by a Riemann sum

$$\int_S \int_T \lambda_{\boldsymbol{\theta}}((u, v) | \mathbf{x}) dv du \approx \sum_{k=1}^{n+p} w_k \lambda_{\boldsymbol{\theta}}((\xi_k, t_k) | \mathbf{x}), \quad (15)$$

where (ξ_k, t_k) are points in $\{(\xi_1, t_1), \dots, (\xi_n, t_n), (\xi_{n+1}, t_{n+1}), \dots, (\xi_{n+p}, t_{n+p})\} \in W$ consisting of the n events of \mathbf{x} and p dummy points, and w_k are quadrature weights such that $\sum_{k=1}^{n+p} w_k = \ell(S \times T)$ where ℓ is Lebesgue measure. This yields an approximation for the log pseudo-likelihood of the form

$$\log PL(\mathbf{x}; \boldsymbol{\theta}) \approx \sum_{(\xi, t) \in \mathbf{x}} \log \lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x}) - \sum_{k=1}^{n+p} w_k \lambda_{\boldsymbol{\theta}}((\xi_k, t_k) | \mathbf{x}). \quad (16)$$

Note that if the set of points $\{(\xi_k, t_k), k = 1, \dots, n+p\}$ includes all the points of $\mathbf{x} = \{(\xi_1, t_1), \dots, (\xi_n, t_n)\}$, we can rewrite (16) as

$$\log PL(\mathbf{x}; \boldsymbol{\theta}) \approx \sum_{k=1}^{n+p} w_k (y_k \log \lambda_{\boldsymbol{\theta}}((\xi_k, t_k) | \mathbf{x}) - \lambda_{\boldsymbol{\theta}}((\xi_k, t_k) | \mathbf{x})), \quad (17)$$

where

$$y_k = \begin{cases} 1/w_k, & \text{if } (\xi_k, t_k) \in \mathbf{x} \text{ is an event,} \\ 0, & \text{if } (\xi_k, t_k) \notin \mathbf{x} \text{ is a dummy point.} \end{cases} \quad (18)$$

The right hand side of (17), for fixed \mathbf{x} , is formally equivalent to the log-likelihood of independent Poisson variables $Y_k \sim \text{Poisson}(\lambda_{\boldsymbol{\theta}}((\xi_k, t_k) | \mathbf{x}))$ taken with weights w_k . Therefore, by using the `glm` function in R ([50]), we can perform the maximum likelihood-based parameter estimation of this Poisson generalized linear model and obtain the maximum value for (17).

Note that in hybrid Geyer model (5), we consider $\lambda(\xi, t) = \lambda_{\beta}(\xi, t) = \beta \mu(\xi, t)$ where $\mu(\xi, t)$ is known or estimated beforehand and β is a parameter to estimate. In summary, the method is as follows.

Algorithm 1

- Generate a set of p uniform dummy points in W and merge them with all the data points in \mathbf{x} to construct the set of quadrature points $(\xi_k, t_k) \in W$ with $k = 1, \dots, n + p$.
160
- Compute the quadrature weights w_k and the indicators y_k defined in (18),
- Compute the sufficient statistics $\mathbf{S}((\xi_k, t_k), \mathbf{x})$ at each quadrature point,
- Fit a log-linear Poisson regression with explanatory variables $\mathbf{S}((\xi_k, t_k), \mathbf{x})$, and offset $\log \lambda(\xi_k, t_k)$ on the responses y_k with weights w_k to obtain estimates $\hat{\boldsymbol{\theta}}$ for the \mathbf{S} -vector and intercept $\hat{\theta}_0$,
165
- Return the maximum pseudo-likelihood-based parameter estimates $\hat{\gamma}_j = \exp(\hat{\theta}_j)$ for $j = 1, \dots, m$ and $\hat{\beta} = \exp(\hat{\theta}_0)$.

We define the quadrature scheme by defining a spatio-temporal partition of W into cubes C_k of equal volumes ν and by using the counting weights proposed in [5]. We then assign to each dummy or data point (ξ_k, t_k) a weight $w_k = \nu/n_k$ where n_k is the number of dummy and data points that lie in the same cube as (ξ_k, t_k) . The number of dummy points should be sufficient for an accurate estimate of the pseudo-likelihood. We follow [5] and start with $p \approx 4n(\mathbf{x})$. Then, we increase it until $\sum_k w_k = \ell(W)$, what can lead to high computational costs.
170

An alternative way to define the quadrature scheme for Algorithm 1 is based on Dirichlet tessellation [5] and the weight of each point is equal to the volume of the corresponding Dirichlet 3D cell. In this paper, we consider cubes because it is less time consuming and provides similar results (see [46] for quadrature schemes comparison of 3D Gibbs point processes).
175

3.2. Logistic likelihood approach

The logistic likelihood method [3] is an alternative for estimating the regular parameters of Gibbs models that is closely related to the pseudo-likelihood method. The Berman-Turner approximation often requires a quite large number
180

of dummy points. Hence, fitting such GLM can be computationally intensive, especially when dealing with a large dataset. [3] formulated the pseudo-likelihood estimation equation as a logistic regression using auxiliary dummy point configurations and proposed a computational technique for fitting Gibbs point process models to spatial point patterns. [29] extended the logistic likelihood approach for spatio-temporal Gibbs point processes and we tailored it to our model.

Let \mathbf{x} be a realization of a spatio-temporal point process defined on W having a density $f_{\boldsymbol{\theta}}$ with respect to the unit rate Poisson process and with conditional intensity function $\lambda_{\boldsymbol{\theta}}(\cdot|\mathbf{x})$. We consider an independent Poisson process for dummy points, with intensity function ρ , and we denote by \mathbf{d} a set of dummy points. We follow [3] (resp. [29]) for choosing ρ of a homogeneous (resp. inhomogeneous) Poisson process in simulation study (resp. application). See [3], for a data-driven determination of ρ and its effect on efficiency and practicability of the method.

By defining $Y(\xi, t) = \mathbb{1}_{\{(\xi, t) \in \mathbf{x}\}}$ for $(\xi, t) \in \mathbf{x} \cup \mathbf{d}$, we obtain independent Bernoulli variables taking one for data points and zero for dummy points. We have

$$Pr(Y(\xi, t) = 1) = \frac{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x} \setminus (\xi, t))}{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x} \setminus (\xi, t)) + \rho(\xi, t)}, \quad (19)$$

By considering the log linearity assumption for the conditional intensity $\lambda_{\boldsymbol{\theta}}(\cdot|\mathbf{x})$ in (12), the logit of $Pr(Y(\xi, t) = 1)$ is

$$\log \frac{\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x} \setminus (\xi, t))}{\rho(\xi, t)} = \log \frac{\lambda(\xi, t)}{\rho(\xi, t)} + \sum_{j=1}^m \theta_j S_j((\xi, t), \mathbf{x} \setminus (\xi, t)), \quad (20)$$

which is a linear model in $\boldsymbol{\theta}$ with offset $\log \frac{\lambda(\xi, t)}{\rho(\xi, t)}$.

Since $\lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x}) = \lambda_{\boldsymbol{\theta}}((\xi, t)|\mathbf{x} \setminus (\xi, t))$ for $(\xi, t) \in \mathbf{d}$, the log logistic likelihood

is defined by

$$\begin{aligned}
\log LL(\mathbf{x}, \mathbf{d}; \boldsymbol{\theta}) &= \sum_{(\xi, t) \in \mathbf{x} \cup \mathbf{d}} Y((\xi, t)) \log \frac{\lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x} \setminus (\xi, t))}{\lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x} \setminus (\xi, t)) + \rho(\xi, t)} \\
&+ \sum_{(\xi, t) \in \mathbf{x} \cup \mathbf{d}} [1 - Y((\xi, t))] \log \frac{\rho(\xi, t)}{\lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x}) + \rho(\xi, t)} \\
&= \sum_{(\xi, t) \in \mathbf{x}} \log \frac{\lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x} \setminus (\xi, t))}{\lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x} \setminus (\xi, t)) + \rho(\xi, t)} \\
&+ \sum_{(\xi, t) \in \mathbf{d}} \log \frac{\rho(\xi, t)}{\lambda_{\boldsymbol{\theta}}((\xi, t) | \mathbf{x}) + \rho(\xi, t)}.
\end{aligned} \tag{21}$$

The maximum of the log-logistic likelihood exists and under regularity condition [4] is unique. Hence, estimation can be implemented in **R** by using the **glm** function.

205 As in *Algorithm 1*, we consider $\lambda(\xi, t) = \lambda_{\beta}(\xi, t) = \beta\mu(\xi, t)$ and we estimate the regular parameters from the following algorithm.

Algorithm 2

- Generate dummy points \mathbf{d} from a Poisson process with intensity function ρ and merge them with all the data points in \mathbf{x} to construct the set of quadrature points $(\xi_k, t_k) \in W$,
- 210 • Obtain the response variables y_k (1 for data points, 0 for dummy points),
- Compute the sufficient statistics $\mathbf{S}((\xi_k, t_k), \mathbf{x} \setminus (\xi_k, t_k))$ at each quadrature point,
- Fit a logistic regression model with explanatory variables $\mathbf{S}((\xi_k, t_k), \mathbf{x} \setminus (\xi_k, t_k))$, and offset $\log(\mu(\xi_k, t_k)/\rho(\xi_k, t_k))$ on the responses y_k to obtain estimates $\hat{\boldsymbol{\theta}}$ for the \mathbf{S} -vector and intercept $\hat{\theta}_0$,
- 215 • Return the parameter estimator $\hat{\gamma} = \exp(\hat{\boldsymbol{\theta}})$ and $\hat{\beta} = \exp(\hat{\theta}_0)$ and in the case where $\mu(\xi_k, t_k)/\rho(\xi_k, t_k)$ is a constant c we have $\hat{\beta} = c^{-1} \exp(\hat{\theta}_0)$.

4. Simulation

220 The simulation algorithms of Gibbs point process models require only computation of the Papangelou conditional intensity which avoids to consider the difficult estimation of the unknown normalizing constant in the density function. Gibbs point process models can be simulated by using Markov chain Monte Carlo (MCMC) algorithms like the birth-death Metropolis-Hastings algorithm 225 [42] that belongs to the large class of Metropolis-Hastings algorithms [27]. In this section, we first present the birth-death Metropolis-Hastings algorithm and secondly we investigate the goodness of parameter estimation of the two approaches introduced before.

4.1. Birth-death Metropolis-Hastings algorithm

230 For \mathbf{x} a spatio-temporal point pattern in W , we can propose either a birth with probability $q(\mathbf{x})$ or a death with probability $1 - q(\mathbf{x})$. For a birth, a new point $(u, v) \in W$ is sampled from a probability density $b(\mathbf{x}, \cdot)$ and the new point configuration $\mathbf{x} \cup (u, v)$ is accepted with probability $A(\mathbf{x}, \mathbf{x} \cup (u, v))$, otherwise the state remains unchanged. For a death, the point $(\xi, t) \in \mathbf{x}$ chosen to be removed 235 is selected according to a discrete probability distribution $d(\mathbf{x}, \cdot)$ on \mathbf{x} , and the proposal $\mathbf{x} \setminus (\xi, t)$ is accepted with probability $A(\mathbf{x}, \mathbf{x} \setminus (\xi, t))$, otherwise the state remains unchanged. For simplicity, we consider $q(\mathbf{x}) = \frac{1}{2}$, $b(\mathbf{x}, \cdot) = 1/\ell(W)$ and $d(\mathbf{x}, \cdot) = 1/n(\mathbf{x})$. By setting $A(\mathbf{x}, \mathbf{x} \cup (u, v)) = \min\{1, r((u, v); \mathbf{x})\}$, and $A(\mathbf{x}, \mathbf{x} \setminus (\xi, t)) = \min\{1, 1/r((\xi, t); \mathbf{x} \setminus (\xi, t))\}$ where $r((u, v); \mathbf{x}) = \frac{\ell(W)}{n(\mathbf{x})+1} \times \lambda((u, v)|\mathbf{x})$ is 240 the Hastings ratio [29], we obtain the following birth-death Metropolis-Hastings algorithm.

Algorithm 3

For $n = 0, 1, \dots$, given $X_n = \mathbf{x}$ (e.g. a Poisson process for $n = 0$), generate X_{n+1} :

- 245 • Generate two uniform numbers y_1, y_2 in $[0, 1]$,
- If $y_1 \leq \frac{1}{2}$ then

- A new point (u, v) is uniformly sampled from a probability density $1/\ell(W)$,
 - Compute $r((u, v); \mathbf{x}) = \frac{\ell(W)}{n(\mathbf{x})+1} \lambda((u, v)|\mathbf{x}), (u, v) \notin \mathbf{x}$.
 - If $y_2 < r((u, v); \mathbf{x})$ then $X_{n+1} = \mathbf{x} \cup (u, v)$ else $X_{n+1} = \mathbf{x}$
- 250
- If $y_1 > \frac{1}{2}$ then
 - Uniformly select a point (ξ, t) in \mathbf{x} according to a discrete probability density $1/n(\mathbf{x})$,
 - Compute $r((\xi, t); \mathbf{x} \setminus (\xi, t)) = \frac{\ell(W)}{n(\mathbf{x})} \lambda((\xi, t)|\mathbf{x} \setminus (\xi, t)), (\xi, t) \in \mathbf{x}$.
 - If $y_2 < 1/r((\xi, t); \mathbf{x} \setminus (\xi, t))$ then $X_{n+1} = \mathbf{x} \setminus (\xi, t)$ else $X_{n+1} = \mathbf{x}$.
 - Note that if $\mathbf{x} = \emptyset$ then $X_{n+1} = \mathbf{x}$.
- 255

This simulation process is repeated a large number of time in order to ensure the convergence of the algorithm to the expected distribution. This number of iterations is unknown a priori and must be determined by the user from practical knowledge and/or diagnostic tools. We choose 20,000 iteration steps in simulation study (70,000 iteration steps in the application study). To investigate the convergence of the algorithm, we use a “trace plot” which shows the evolution of the number of points at each iteration of *Algorithm 3*. Thus, we check that the number of points in the simulated point pattern is stabilized (see [42, 31] for more details).

260

265

4.2. Simulation study

We compare the performance of the pseudo-likelihood and logistic likelihood approaches on the spatio-temporal multi-scale Geyer point process. We generate 100 simulated realizations in the unit cube from three models. The first one exhibits strong clustering (*Model 1*), the second one exhibits small scale inhibition and large scale clustering (*Model 2*) and the third one exhibits inhibition (*Model 3*). Model parameters are reported in Table 1. We consider a burn-in period of 20,000 steps in *Algorithm 3*. Figure 1 shows one realization of each model.

270

Table 1: Parameters of the three multi-scale Geyer point process models used in simulation study.

Model	Values of parameter				
	Regular parameters		Irregular parameters		
	λ	γ	r	q	s
<i>Model 1</i>	70	(1.5,1.5)	(0.05,0.1)	(0.05,0.1)	(2,2)
<i>Model 2</i>	100	(0.5,1.5)	(0.05,0.1)	(0.05,0.1)	(1,3)
<i>Model 3</i>	200	(0.8,0.8)	(0.05,0.1)	(0.05,0.1)	(1,1)

Figure 1: Realizations of *Model 1* (left); *Model 2* (middle); *Model 3* (right).

275 According to [3], we generate a spatio-temporal Poisson process with inten-
sity $\rho = 4n(\mathbf{x})$ (resp. $4n(\mathbf{x})/\ell(W)$) as dummy points in *Algorithm 1* (resp.
Algorithm 2). For each model, we compute the root mean square error (RMSE)
of each set of estimated parameters (Table 2) and plot the related boxplots (Fig-
ure 2). In Table 2 the lowest RMSE value is in bold and in Figure 2 the true
280 values are represented by horizontal red lines. Both RMSE and boxplots show
that the logistic likelihood approach performs better than the pseudo-likelihood
approach for any model.

Note that in the spatial framework, [3] showed that for large datasets the

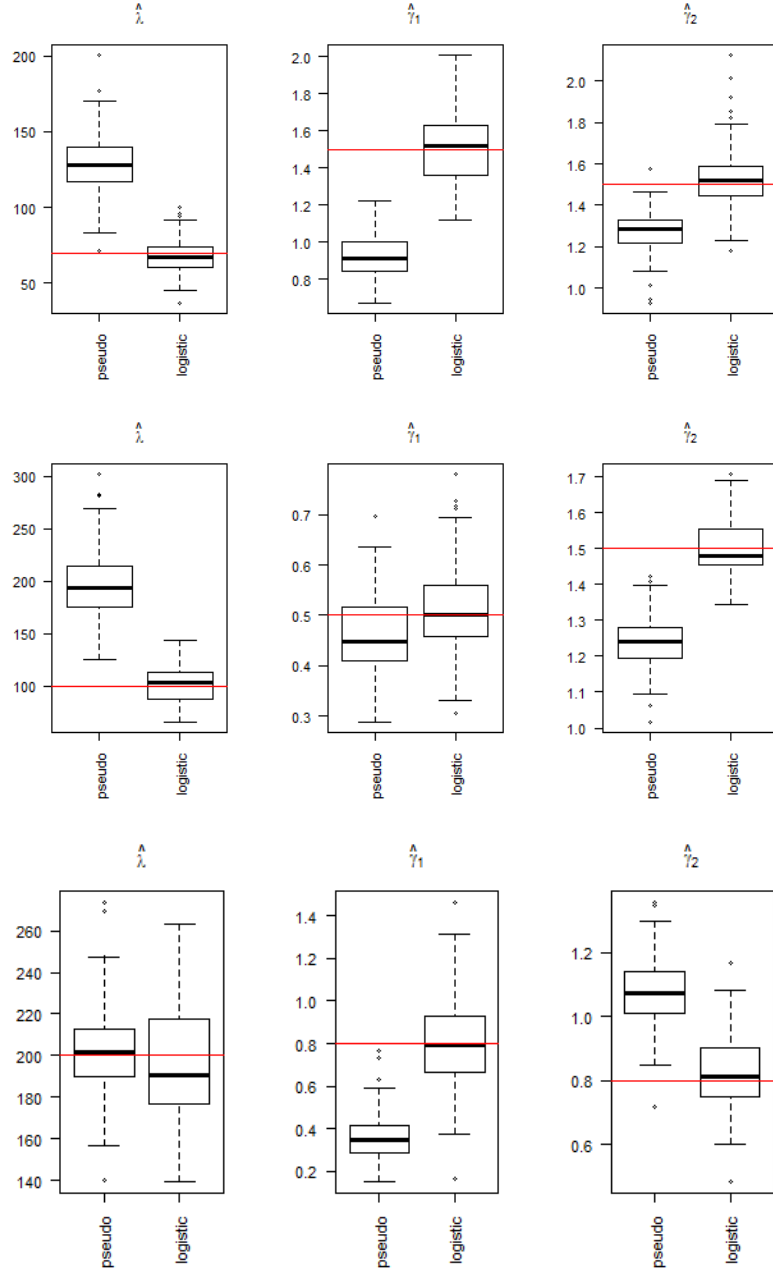

Figure 2: Boxplots of regular parameters estimated from the pseudo-likelihood and logistic likelihood approaches for *Model 1* (first row), *Model 2* (second row) and *Model 3* (third row). True values are represented by horizontal red lines.

logistic likelihood method is preferable than the pseudo-likelihood method as it
 285 requires a smaller number of dummy points and performs quickly and efficiently.
 [18] and [15] investigated a similar comparison when these methods are regu-
 larized (i.e. using an approach with a simultaneous parameter estimation and
 variable selection by maximizing a penalized likelihood functions). [29] found
 the advantage of the logistic likelihood approach for the spatio-temporal multi-
 290 scale area-interaction point process model. We here confirm this advantage for
 the spatio-temporal multi-scale Geyer point process model.

5. Application to forest fire occurrences

Economic and ecological disasters caused by wildfires in the world have led
 the scientific community to develop many novel statistical analysis and mod-
 295 elling wildfire occurrences to better understand their behaviors. In this section,
 we focus on the modelling of forest fire occurrences in the Bouches-du-Rhône
 county (Southern France) between 2001 and 2015.

Several statistical studies have shown the influence of environmental and
 meteorological factors on forest fire occurrences. In the French Mediterranean
 300 basin, [47] fit a spatio-temporal log-Gaussian Cox process model for forest fire
 occurrences with a log-linear intensity depending on spatio-temporal land use
 and weather covariates. [25] investigated the impact of the different covariates
 on the number of fires using multivariate analysis and [23] explored the influ-
 ence of land cover covariates, temperature and precipitation on the probability
 305 of event occurrence. In addition to the spatio-temporal clustering of events in-
 duced by some covariates, [23] detected spatio-temporal interaction structures
 at different scales and notably an inhibitive effect that arises locally in time and
 space after wildfires as we expect lesser occurrences at these locations during a
 vegetation regeneration period.

310 We propose to fit the spatio-temporal hybrid Geyer point process model (5)
 on wildfire occurrences to take into account both the inhomogeneities induced
 by covariates and the multi-scale structure of interactions.

5.1. Data

Our data set is of the form (ξ_i, t_i) , $i = 1, \dots, 434$, where (ξ_i, t_i) corresponds
 315 to a wildfire with more than 1 *hectare* of burnt surface spatially indexed by
 a DFCI² cell center ξ_i in the Lambert 93 projection system and year $t_i \in$
 $\{2001, \dots, 2015\}$. To avoid duplicated points we uniformly jittered ξ_i in its
 DFCI cell. We refer the reader to [23] and [47] for further information on the
 data. Whilst forest fires are daily reported, we consider here the yearly scale,
 320 as done in many works (see e.g. [56, 54, 55]), because of the small number
 of reports and to optimize computation time in model fitting and validation
 steps. Figure 3 plots locations of forest fires (left panel) and yearly number
 of occurrences (right panel). It shows some clustering at short and medium
 spatial distances. Note that there exist two particular areas without any fire
 325 occurrences as they correspond to a lake (center) and marshlands (South-West).
 The number of fires slightly exponentially decreases in time over the 15 years,
 mainly due to improvements of fire-fighting resources.

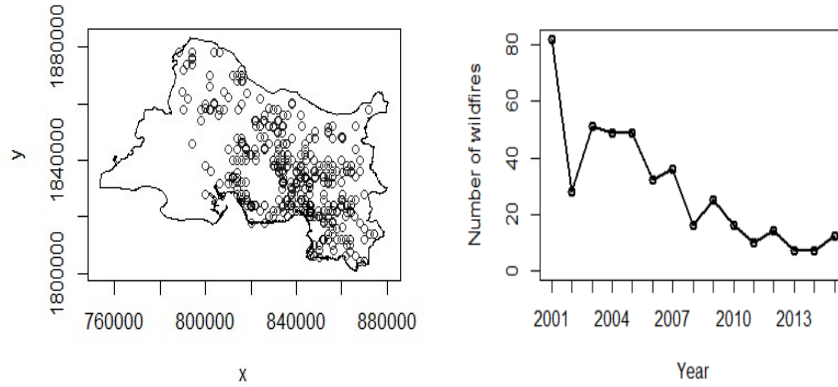

Figure 3: (Left) Forest fire locations in UTM coordinate system (distance in meters), with more than 1 *hectare* of burnt area, recorded during the years 2001 to 2015 in the Bouches-du-Rhône county in France. (Right) Number of recorded forest fires per year.

²district units for fire management strategies, see [47]

We consider the same framework as in [23] and restrict our attention to the following covariates: water coverage, elevation, coniferous cover and building cover as spatial covariates and temperature average, precipitation as spatio-temporal covariates. Hence, we can consider these covariates as good proxies of the main environmental, climatic and human factors. Maps of covariates are shown in Figure 4 in 2001.

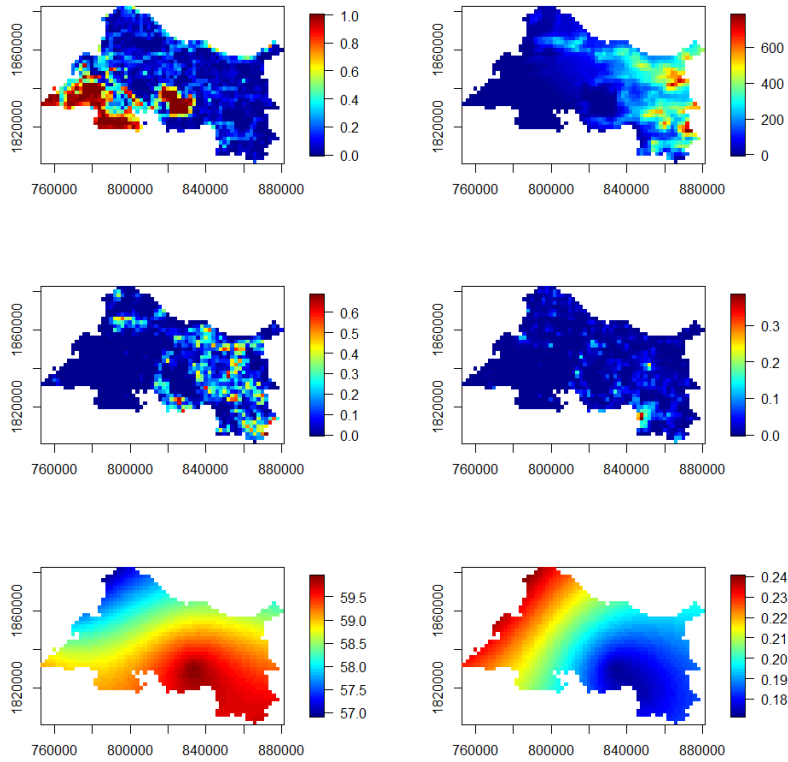

Figure 4: Maps of covariates: water coverage (top left), elevation (top right), coniferous cover (middle left), building cover (middle right), temperature average (bottom left) and square root of precipitation (bottom right) in 2001.

5.2. Model fitting

335 Here we first estimate the spatio-temporal trend and then fit the multi-scale spatio-temporal Geyer model to forest fire occurrences. This two-step model fitting procedure follows our assumption that most forest fire occurrences are firstly due to environmental and meteorological conditions and secondly due to unobserved pairwise interactions. This technique will allow to see the benefits
340 of the multi-scale interaction structure in our hybrid model compared to an inhoogeneous Poisson model with the same spatio-temporal trend.

5.2.1. Spatio-temporal trend estimation

We express the spatio-temporal trend (5) as $\lambda(\xi, t) = \beta\mu(\xi, t)$ where $\log \mu(\xi, t)$ is assumed to linearly depend on covariates:

$$\log \mu(\xi, t) = \beta_0 + \sum_{k=1}^4 \beta_k^S Z_k^S(\xi) + \sum_{l=1}^2 \beta_l^{ST} Z_l^{ST}(\xi, t) + \alpha t \quad (22)$$

with $Z_k^S(\xi)$, $k = 1, \dots, 4$, the spatial covariates, $Z_l^{ST}(\xi, t)$, $l = 1, 2$, the spatio-temporal covariates and αt a decreasing trend of fire counts over time. Because
345 the covariates are known at a fixed discretization scale, $\mu(\xi, t)$ does not vary for points ξ inside the same DFCI unit with a time t corresponding to the same year. By consequence, we can restrict our attention on DFCI grid cell centers $\xi_i, i = 1, \dots, 1320$ and years $t_j = 2001, \dots, 2015$ for $j = 1, \dots, 15$, and we consider a Poisson response for our model $N_{ij} | \mu(\xi_i, t_j) \sim \text{Poisson}(\mu(\xi_i, t_j))$,
350 where N_{ij} is the number of forest fires in i^{th} DFCI cell at year t_j . The coefficient β will be estimated simultaneously with the others regular parameters by the logistic likelihood approach. Table 3 reports the coefficients $\beta_0, \beta_k^S, \beta_l^{ST}$ and α estimated as in [23] and [47]. The sign indicates if covariates favour (if positive, like coniferous, building and temperature) or prevent (if negative, like water, elevation, precipitation and time) fire occurrences. All covariates are globally
355 significant and results are consistent with previous works [25, 23, 47] for this county. Note that p -values have been computed during the trend fitting under a Poisson model and not for the overall fitting of forest fire occurrences under our

spatio-temporal hybrid Geyer saturation process. Thus, we might obtained more
 360 significance of the covariates than under our hybrid Geyer saturation model.

Table 3: Estimated coefficients, standard errors and p -values based on two-tailed Student's t-tests of significant differences from zero.

Covariates	Coefficients	Estimates	Standard error	p -value

Time	α	-0.14	0.001	$< 2 \times 10^{-16}$ ***

5.2.2. Parameters estimation

There is no common method for estimating irregular parameters in spatial
 or spatio-temporal Gibbs point process models. Here we considered several
 combinations of ad-hoc values within a reasonable range and select the optimal
 365 irregular parameters according to the Akaike's Information Criterion (AIC) of
 the fitted model.

[6] suggest that the spatial interaction radius r of the Geyer saturation point
 process should be between 0 and the maximum nearest neighbor distance, about
 8000 *meters* for our dataset. For the temporal radius q , we consider small
 370 values to be in accordance with the natural phenomena of forest fire occurrences.
 Finally, for the saturation parameter s , we have $n(C_r^q(\xi_i, t_i); \mathbf{x}) \leq s$ for all
 $(\xi_i, t_i) \in \mathbf{x}$. Hence, for any pair (r, q) , we set $s = \max_{1 \leq i \leq n} n(C_r^q(\xi_i, t_i); \mathbf{x})$.

According to the former section, we use the logistic likelihood method and
Algorithm 2 to estimate the regular parameters. We simulate dummy points
 375 from an inhomogeneous Poisson point process with intensity $\rho(\xi, t) = C\mu(\xi, t)/\nu$
 where $C = 4$ by a classical rule of thumb in the logistic likelihood approach and
 $\nu = 2000 \times 2000 \times 1$ (area of a DFCI cell multiplied by 1 year).

We fitted the spatio-temporal multi-scale Geyer point process model for a
 range of ad-hoc values $(r_j, q_j) \in [0, 8000] \times \{1, 2, 3, 4, 5\}$, and their corresponding

Table 4: Parameter estimates for $m = 4$.

	Irregular parameters			
	500	2000	5000	7500
r				
q	1	2	3	4
s	4	7	27	57
Estimated regular parameters and 95% confidence intervals				
$\hat{\beta} = 0.66$	$\hat{\gamma}_1 = 2.73$	$\hat{\gamma}_2 = 0.93$	$\hat{\gamma}_3 = 1.07$	$\hat{\gamma}_4 = 0.98$
[0.442, 0.968]	[1.818, 3.405]	[0.820, 0.994]	[1.020, 1.120]	[0.962, 1.011]

values of s_j , $j = 1, \dots, m$, with varying m in $\{1, 2, 3, 4, 5\}$. The minimum AIC is obtained for the combination given in Table 4. Estimated regular parameters γ_j associated with their 95% bootstrap confidence intervals show strong clustering at very short distances, weak repulsion (resp. clustering) at small (resp. medium) scale, and randomness at large scale. Another methodology for testing the significance of γ_j parameters from 1 could be to extend the pseudo-likelihood or composite likelihood ratio test introduced in [8] to the spatio-temporal case.

5.3. Model validation

We validate our fitted model from several Monte Carlo tests using statistics based on the spatio-temporal inhomogeneous K -function [22]. First, we generate $n_{sim} = 99$ simulations from our fitted hybrid Geyer model (5) by *Algorithm 3* with a burn-in period of 70,000 steps, representing realizations from our null hypothesis. Then, we compute the spatio-temporal inhomogeneous K -function for the observed and simulated point patterns, denoted respectively by $\hat{K}_{obs}^{inh}(h_s, h_t)$ and $\hat{K}_i^{inh}(h_s, h_t)$, $i \in \{1, \dots, n_{sim}\}$, with an estimated separable intensity function obtained by kernel smoothing. For each value of the spatio-temporal distance (h_s, h_t) , lower (L) and upper (U) critical envelopes of the summary statistics are computed locally

$$L(h_s, h_t) = \min_{1 \leq i \leq n_{sim}} \hat{K}_i^{inh}(h_s, h_t), \quad U(h_s, h_t) = \max_{1 \leq i \leq n_{sim}} \hat{K}_i^{inh}(h_s, h_t). \quad (23)$$

In addition to these local envelopes, we compute local and global p -values as in [61, 57] in order to respectively detect spatio-temporal distances where the

departure from the null hypothesis is the most significant and the overall adequacy of our model. Let $E(h_s, h_t)$ and $V(h_s, h_t)$ denote the mean and variance of $\{\hat{K}_1^{inh}(h_s, h_t), \dots, \hat{K}_{n_{sim}}^{inh}(h_s, h_t), \hat{K}_{obs}^{inh}(h_s, h_t)\}$. We define the local p -value for each pair (h_s, h_t) by

$$p(h_s, h_t) = \frac{1 + \sum_{i=1}^{n_{sim}} \mathbb{1}\{T_i(h_s, h_t) > T_{obs}(h_s, h_t)\}}{n_{sim} + 1}, \quad (24)$$

where $T_i(h_s, h_t)$ (resp. $T_{obs}(h_s, h_t)$) denotes the local statistic T computed from the i^{th} simulation (resp. the data) at (h_s, h_t) . The local statistic is defined by

$$T(h_s, h_t) = \sqrt{\frac{(\hat{K}^{inh}(h_s, h_t) - E(h_s, h_t))^2}{V(h_s, h_t)}}. \quad (25)$$

The global test combines the information for all spatial and temporal distances. We define the test statistic

$$\tilde{T} = \int_0^{h_{t,max}} \int_0^{h_{s,max}} T(h_s, h_t) dh_s dh_t, \quad (26)$$

where $h_{s,max}$ and $h_{t,max}$ are user-specific maximum spatial and temporal distances which are preferable to choose close to the (expected) range of interaction of the underlying point process. [31] recommends to compare the results for several values of $h_{s,max}$ and $h_{t,max}$. The p -value of the global test is then given by

$$p_{global} = \frac{1 + \sum_{i=1}^{n_{sim}} \mathbb{1}\{\tilde{T}_i > \tilde{T}_{obs}\}}{n_{sim} + 1}.$$

Figure 5.a) shows the spatio-temporal inhomogeneous K function computed on our dataset (dark grey) and the envelopes obtained from our hybrid Geyer model (light grey); $\hat{K}_{obs}^{inh}(h_s, h_t)$ lies inside the envelopes, meaning that the fitted model seems to describe properly the spatio-temporal structure of the data. This is confirmed by local p -values at any distances (Figure 5.b). Global p -values are given in Figure 5.c) for any combination of $h_{s,max}$ and $h_{t,max}$. Again, it shows that our fitted model is validated.

In addition, we also compute global envelopes and p -value of the spatio-temporal \hat{K}^{inh} functions based on the Extreme Rank Length (ERL) measure defined in [37] and implemented in the R package GET [43]. The main advantage

Figure 5: Temporal separations h_t are in *year* and spatial distances h_s are in *kilometer*. a) Envelopes of the spatio-temporal inhomogeneous K -function for the simulated spatio-temporal multi-scale Geyer point process according to the estimated parameters. b) Image plot of the local p -value. c) Image plot of the global p -value for any pairs of $(h_{s,max}, h_{t,max})$.

is that the resulting p -value will not depend on a priori parameters as in the definition of p_{global} with the $h_{s,max}$ and $h_{t,max}$ values. For each point pattern, we consider the long vector T_i , $i = 1, \dots, n_{sim}$ (resp. T_{obs}) merging the $K_i^{inh}(\cdot, h_t)$ (resp. $K_{obs}^{inh}(\cdot, h_t)$) estimates for all considered values h_t . The ERL measure of vector T_i (resp. T_{obs}) of length n_{st} is defined as

$$E_i = \frac{1}{n_{ns}} \sum_{j=1}^{n_{st}} \mathbb{1}\{R_j \prec R_i\},$$

where R_i is the vector of pointwise ordered ranks and \prec is an ordering operator [37, 43]. The final p -value is obtained by

$$p_{erl} = \frac{1 + \sum_{i=1}^{n_{sim}} \mathbb{1}\{E_i \geq E_{obs}\}}{n_{sim} + 1}.$$

The global p -value p_{erl} is equal to 0.34 consolidating previous results and validating our hybrid Geyer model.

Note that we did the same tests for 99 simulations of an inhomogeneous Poisson process with intensity $\mu(\xi, t)/(2000 \times 2000 \times 1)$ (22). This model has

400 been rejected at the level 5%, with a median global p -value equals to 0.04.
The p_{ert} value is equal to 0.04 under the Poisson assumption rejecting also this
baseline model.

Conclusion

Due to the capability of Gibbs point processes to cover prevalent struc-
405 tures (inhibition, randomness and clustering), the hybridization approach al-
lows to introduce new Gibbs models combining several structures at different
scales. In this paper, we defined the spatio-temporal multi-scale Geyer satura-
tion point process model and detailed the classical statistical inference meth-
ods and MCMC simulation techniques that we have extended to the spatio-
410 temporal framework and implemented in R code³ that will be added to the `stpp`
package [24]. Our simulation study highlighted a better goodness-of-fit of pa-
rameters for the logistic likelihood approach compared to the pseudo-likelihood
approach. Finally, we illustrated the interest of using this model on a spatio-
temporal dataset of forest fire locations associated with environment covariates.
415 The model validation shows that our model captures the multi-scale interaction
structure inherent to forest fire occurrences.

In this paper, we focused our attention on the definition of a new hybrid
Gibbs model, the inference methods and MCMC simulation algorithms that we
needed to adapt to the spatio-temporal context. Some of our choices can be
420 discussed and eventually improved in future works, notably in our application
to forest fire occurrences which is not presented as an in-depth study but as an
illustration of the model fitting on real data.

In our application study, we considered a log-linear form for the trend de-
pending on covariate information. We chose a two-step procedure for estimating,
425 at first, the trend coefficients and then the regular parameters of the interaction
function. Our knowledge on forest fire mechanisms guided this choice because

³<http://edith.gabriel.pagesperso-orange.fr/software.html>

the main driver of occurrence locations is the environmental heterogeneity and the secondary one is the interaction phenomena. The trend is estimated at the spatial DFCI scale and at the yearly one, corresponding to our covariate resolution. In that way, we estimated a global trend at a medium scale whereas
430 the interaction parameters are estimated at the point locations and represent a local interaction behavior at a fine scale. This procedure could be improved by incorporating variable selection methods, e.g. via regularization [15, 18].

Our two-step estimation procedure allows us to provide confidence intervals
435 for both the trend coefficients and the regular parameters. We notice that some parameters γ_j are closed to one. Here we consider a bootstrap estimate of the confidence interval for each γ_j . We could further test departure from one by extending the adjusted composite likelihood ratio test [8] to the spatio-temporal framework. Indeed, [8] proposed a likelihood ratio test for spatial Gibbs point
440 process models fitted by maximum pseudo-likelihood. They discussed that implementing other composite likelihood as the logistic likelihood would provide a better composite likelihood ratio test. Estimating diagnostics related to the logistic likelihood requires to estimate the variance-covariance matrix of the logistic score and the sensitivity matrix. [3] provide consistent estimators of these
445 quantities. The extension to the spatio-temporal framework is a full-blown work that also involves efficient implementation.

For the choice of irregular parameters, because the likelihood is not differentiable with respect to them, we used a maximum profile likelihood approach based on the logistic likelihood estimation procedure and AIC values for model
450 selection. Introduced for the pseudo-likelihood estimates in [1] and applied to the logistic likelihood approach by us using the results in [3], this method consists in fixing irregular parameters and maximizing the composite likelihood with respect to the regular ones. This technique is a computationally-intensive method. Thanks to a preliminary spatio-temporal exploratory analysis of the
455 interaction ranges done with the inhomogeneous pair correlation function g , the maximum nearest neighbor distance and the temporal autocorrelation function, we chose few configurations of feasible values for the nuisance parameters m, r_j ,

q_j and s_j , $j = 1 \dots m$. Considering more values would be very time-consuming and developing a new estimation method would be a subject in its own right.

460 During the model validation procedure, we could use the global envelope tests based on the ERL measure to assess the goodness-of-fit of submodels with fewer irregular parameters to be parsimonious.

Our model can be used in many fields, like seismology and epidemiology for example, because several mechanisms exhibit interaction between points at multiple scales in space and time. Relying on this work, we can also develop
465 hybrid models with different density structures. Indeed, although it was not necessarily highlighted here, we know that forest fires with large burnt areas avoid future fire occurrences during a vegetation regeneration period. Such cases of strong inhibition may be modeled by hybrid Gibbs point processes with
470 a hardcore component like the hybrid Geyer hardcore point process. We recently extended our work to this model.
