Abstract

Nutrient deficiency alters growth and the production of high-quality nutritious food. In Citrus crops, rootstock technologies have become a key tool for enhancing tolerance to abiotic stress. The use of doubled diploid rootstocks can improve adaptation to lower nutrient inputs. This study investigated leaf structure and ultrastructure and physiological and biochemical parameters of common clementine scions (C) grafted on diploid (2x) and doubled diploid (4x) Carrizo citrange (C/CC2x and C/CC4x) and Citrumelo 4475 (C/CM2x and C/CM4x) rootstocks under optimal fertigation and after seven months of nutrient deficiency. Rootstock ploidy level had no impact on structure but induced changes in the number and/or size of cells and some cell components of common clementine leaves under optimal nutrition. Rootstock ploidy level did not modify gas exchanges in Carrizo citrange but induced a reduction in the leaf net photosynthetic rate in Citrumelo 4475. By assessing foliar damage, changes in photosynthetic processes and malondialdehyde accumulation, we found that C/CM4x were less affected by nutrient deficiency than the other scion/rootstock combinations. Their greater tolerance to nutrient deficiency was probably due to the better performance of the enzyme-based antioxidant system. Nutrient deficiency had similar impacts on C/CC2x and C/CC4x. Tolerance to nutrient deficiency can therefore be improved by rootstock polyploidy but remains dependent on the rootstock genotype.

Introduction

Fruit crops, especially citrus fruits, require large amounts of fertilizers to ensure good production and fruit quality. Today, the challenge for sustainable agriculture, and particularly organic agriculture, is to reduce the use of inputs in crops. Reducing inputs optimizes the economic outcome while limiting the environmental impact.

Water and minerals absorbed by roots in the soil are essential for plant development, growth and reproduction. Fourteen minerals are considered essential and these can be divided into two groups: the macroelements (N, K, P, Ca, Mg and S) which are constituents of organic matter (proteins, nucleic acids) or play a strong osmotic role, and microelements (Zn, Cu, Fe, Mn, B, Mo, Cl and Ni), which are only involved as specific cofactors or constituents of certain enzymes^{1–3}. Mineral-deficient plants present various visual symptoms, such as necrosis, chlorosis, dark green foliage, or stunted growth⁴. Essential mineral deficiency alters plant primary metabolism and this disrupts the physiological and biochemical processes leading to changes in leaf structure and ultrastructure^{5,6}. Moreover, cells must cope with an overproduction of reactive oxygen species (ROS) such as singlet oxygen (O^*), hydroxyl radicals (OH^*), superoxide anion ($O_2^{\cdot-}$) and hydrogen peroxide (H_2O_2) which cause membrane leakage due to lipid peroxidation and damage to proteins and nucleic acids^{7–9}. As a result, ROS defence mechanisms are activated by a set of antioxidant compounds (metabolites such as ascorbate and proline) and antioxidant enzymes (superoxide dismutase (SOD), catalase (CAT), ascorbate peroxidase (APX) and dehydroascorbate reductase (DHAR)). Adapted genotypes are therefore sought in order to propose cultural itineraries more suitable to low input conditions.

In citrus crops, improving the performance of varieties is based on the scion/rootstock combination forming the aerial parts and roots of the plant, respectively. The impact of the rootstock on the scion lies in its influence on flowering, fruit quality, canopy size, and resistance, among other parameters¹⁰. Good relations between rootstock and scion are essential for the efficient translocation of water and mineral nutrients and to promote biomass production and tolerance to biotic and abiotic factors, such as nutrient deficiency^{11,12}. Improved root system vigour in citrus rootstocks results in increased soil nutrient and water uptake^{13,14}. All modern cultivated varieties of citrus are now grafted on diploid rootstocks and therefore have two sets of chromosomes in their genetic heritage. However, incomplete mitosis of somatic embryos may occur in seedlings of diploid (2x) apomictic genotypes with formation of doubled diploid (4x) genotypes¹⁵.

Recent advances have shown that rootstock tetraploidy can improve the tolerance of a scion. Grafting of Valencia Delta sweet orange (*Citrus sinensis* L.) on 4x rangpur lime (*Citrus limonia*) rootstock was found to improve its tolerance to water stress by changing patterns of gene expression in Rangpur lime citrus roots regulating adaptation to water deficit¹⁶. Natural chilling stress tolerance associated with a robust antioxidant system was also enhanced in common clementine (*Citrus clementina* Hort. ex Tan) grafted with Carrizo citrange (*Citrus sinensis* Osb. × *Poncirus trifoliata* L. Raf.) 4x rootstock¹⁷. Chromium tolerance of Kinnow mandarin (*Citrus nobilis* Lour x *Citrus deliciosa* Ten) grafted on three 4x rootstocks (*Poncirus trifoliata* [L.], *Citrus reshni*, and *Citrus limonia* Osbeck.) may be attributed to chromium sequestration in roots with lower transfer to leaves in 4x rootstocks¹⁸. The use of rootstocks better adapted to environmental constraints seems to be a promising eco-friendly strategy.

Many *Citrus* genotypes are used as rootstock for citrus cultivation. Genotypes belong either to the *Citrus* genus such as Volkamer lemon or are obtained by hybridization between *Citrus* and *Poncirus* genus progenitors such as Citrumelo 4475 and Carrizo citrange. Volkamer lemon which is used as rootstock for lemon, is adapted to dry, calcareous and saline soils and presents tolerance to Tristeza, cachexia and exocortis. Citrumelo 4475 imparts cold tolerance to the scion. Citrange Carrizo is frequently used in acidic and neutral soils but not in dry areas because of its limited performance under drought conditions. These two genotypes inherited Tristeza tolerance from their Trifoliolate orange progenitor and give clementine varieties that produce a high yield and fruit quality¹⁹.

In a previous study, we compared leaf structure and ultrastructure under nutrient deficiency of two genotypes used worldwide as rootstock for citrus cultivation, the Citrumelo 4475 (*Citrus paradisi* L. Macf. × *Poncirus trifoliata* L. Raf.) and Volkamer lemon (*Citrus limonia* Osb.) with both 2x and 4x genotypes²⁰. Results showed an increase in tolerance to nutrient deficiency in 4x genotypes. Doubled diploid genotypes presented less degradation of ultrastructural components such as chloroplasts, thylakoids, mitochondria and starch grains associated with a smaller decrease in leaf net photosynthetic rate (P_{net}), stomatal conductance (g_s) and chlorophyll fluorescence (F_v/F_m) compared to 2x genotypes.

The higher tolerance to nutrient deficiency was linked to the reduced accumulation of malondialdehyde (MDA) and H_2O_2 in Citrumelo 4475 4x than in the 2x, implying a more efficient antioxidant system in the 4x genotype. However, few differences in the antioxidant system and oxidative status were observed between 2x and 4x Volkamer lemons.

The aim of this study was therefore to determine the impact of rootstock ploidy level on the 2x common clementine scion during nutrient deficiency. We selected common clementine grafted on two rootstocks used worldwide for clementine cultivation, i.e. Citrumelo 4475 (C/CM2x) and Carrizo citrange (C/CC2x) in both 2x and 4x types (C/CM4x and C/CC4x, respectively). The effect of rootstock ploidy level on common clementine scions under nutrient deficiency was investigated by studying common clementine leaf structure and ultrastructure and physiological and biochemical parameters.

Results And Discussion

Effect of rootstock ploidy level on anatomical properties of common clementines under control conditions

Whatever the rootstock genotype and ploidy level, microscopic examination of leaf surface imprints confirmed the presence of stomata only on their abaxial surface that were surrounded by ordinary epidermal cells²⁹ (anomocytic organization) (Fig. 1). Rootstock tetraploidy did not induce any changes in the location of stomata or the epidermal cell structure of common clementine leaves. This agrees with this anomocytic organization observed on leaves of tetraploid seedlings²⁰.

Stomata size was unchanged in C/CM4x and C/CC4x combinations. Conversely, stomata density decreased and ostiole sizes increased in C/CC4x compared to C/CC2x combinations (Table 1). Studies have shown a positive correlation between stomata and ostiole size and a negative correlation between stomata density and ploidy level in both 4x ungrafted genotypes and 3x clementine in comparison to their 2x counterparts^{20,29,30}. Our study showed that 4x rootstocks had no effect on stomata sizes in 2x common clementine scions and a non-systematic impact on ostiole size and stomatal density, putatively through changes in hydraulics or mineral inputs. The decrease in stomatal density caused by rootstock tetraploidy in the C/CC4x combination was not associated with any changes in gas exchanges compared to its C/CC2x counterpart (Table 1; Fig. 1 and 5). The increase in ostiole size in the C/CC4x combination compared to its C/CC2x counterpart suggests an adjustment of the stomata opening to compensate for the reduced stomatal density and maintain stomatal conductance³¹. This adjustment could be due to the considerable degradation of starch grains in the guard cells in the first hour of light contributing to a rapid increase in the opening of the stomata in parallel with the activation of membrane ion transport^{32,33}.

Despite identical physical stomatal attributes between C/CM2x and C/CM4x combinations, analysis of the gas exchange parameters revealed a decrease of P_{net} in the C/CM4x combination (Table 1; Fig. 1 and

5). Other factors than leaf structure therefore appear to be involved in the regulation of photosynthesis in the C/CM4x combination.

At ultrastructural level, rootstock tetraploidy initiated changes in the number and size of the main cell components of the 2x common clementine leaves (Tables 2 and 3). Cell size and thickness in both palisade and spongy mesophylls were reduced in C/CC4x compared to C/CC2x, whereas they increased in C/CM4x compared to C/CM2x (Tables 2 and 3; Fig. 2 and 3). These ultrastructural modifications were the only identical changes in C/CM4x and the ungrafted rootstock counterpart²⁰. In contrast to its ungrafted counterpart, C/CM4x showed a lower P_{net} and similar chloroplast numbers to C/CM2x²⁰ (Tables 2 and 3; Fig. 2, 3 and 5A). Chloroplast enlargement in palisade mesophyll brought about by rootstock tetraploidy in common clementine leaves was not associated with an increase in chloroplast numbers. This phenomenon appears to reduce photosynthetic capacity³⁴. Overall, under optimal conditions and depending on the rootstock genotypes, the structural and/or ultrastructural modifications of common clementine leaves induced by rootstock tetraploidy could either compensate each other with no change in gas exchanges or induce a modification of gas exchanges. The number and size of transitory starch grains and mitochondria were either reduced or similar between 2x and 4x scion/rootstock combinations in palisade and spongy mesophylls (Tables 2 and 3; Fig. 2 and 3). The number of plastoglobuli increased in C/CM4x and C/CC4x compared to C/CM2x and C/CC2x in the chloroplasts of the palisade and spongy mesophylls. Only the C/CM4x plastoglobuli were larger than those of its 2x counterpart (Tables 2 and 3; Fig. 2 and 3). Thus, rootstock tetraploidy involved a potential increase in lipid (plastoquinone-9 (PQ-9), plastoquinol-9 (PQ-9H2) and α -tocopherol (α -T)) reserves that could not be deposited in the thylakoids of chloroplasts.

Rootstock tetraploidy can induced modifications in the number and/or size of the investigated ultrastructural components.

Differences in photosynthetic properties and redox status of scion/rootstock combinations under nutrient stress could be related to their leaf and cell anatomy

Complete starvation resulted in a significant decrease in N but similar or higher levels of P, K, Mg, Ca and Na than controls in all scion/rootstock combinations (Table 4). A concentration effect induced by the transfer of N to other tree areas could explain the increase in P, K and Mg contents in all scion/rootstock combinations³⁵. Leaf chlorosis occurs when plants do not have the nutrients needed for chlorophyll synthesis, which in turn affects the photosynthetic efficiency³⁶. However, the decrease in N, which was an important factor in chlorosis, was similar in all scion/rootstock combinations (Table 4). C/CM4x showed less chlorosis as indicated by its light green colour compared with the yellow colour of other scion/rootstock combinations (Fig. 4). These results suggest a better integrity of chlorophyll content

probably related to a better protection against ROS^{37–39}. The improvements in the redox status of scions by tetraploid rootstocks is probably linked to an improvement in photosynthesis.

Chlorosis was associated with structural and ultrastructural foliar changes and a disruption of photosynthetic properties in all scion/rootstock combinations^{6,40} (Tables 1, 2 and 3; Fig. 5). At structural level, stomata and ostioles of all scion/rootstock combinations showed a narrowing which was associated with an increase in density (except in C/CC2x) response to nutrient deficiency (Table 1; Fig. 1). The rootstock apparently has a different effect on the structural components of common clementine leaves depending on genotype and/or ploidy level. P_{net} and g_s decreased concomitantly in all scion/rootstock combinations under nutrient deficiency (Fig. 5A-B). These results suggest a critical role of stomatal structure in the process of CO₂ availability⁴¹. However, the smaller decrease in P_{net} , g_s and F_v/F_m in C/CM4x than in other scion/rootstock combinations (Fig. 5) implies that other factors than stomata are needed to sustain photosynthesis^{42–44}.

At ultrastructural level, nutrient deficiency resulted in cell size enlargement (except in C/CM2x spongy mesophyll), thylakoid with grana degradation and a decrease in chloroplast size in leaf mesophylls of all scion/rootstock combinations (Tables 2 and 3; Fig. 2 and 3). Similar results were recorded in other plants under conditions of high light stress, infection, dark-induced senescence or total nutrient deficiency^{6,20,45,46}. Chloroplast degradation may be due to the significant decrease in N in the mature leaves of each scion/rootstock combination following the extensive remobilization of N present in the cell to younger leaves or storage areas during nutrient deficiency^{47,48} (Tables 2 and 3; Fig. 2 and 3).

The overproduction of reactive oxygen species (ROS) leads to alterations in the integrity of the membrane structures of cells, chloroplasts or thylakoids by a process called lipid peroxidation, one of the indicators of which is malondialdehyde (MDA). The lower MDA content in C/CM4x compared to other scion/rootstock combinations was consistent with the reduced damage to ultrastructure (Tables 2 and 3; Fig. 2, 3, and 6D). Thylakoid size and structure is dependent on the formation of PSII-LHCII supercomplexes⁴⁹. In C/CM4x, the lower decrease in F_v/F_m suggests a more limited degradation of the PSII-LHCII supercomplexes reducing the disruption of electron transport for the photosynthetic reaction and thus the production of ROS⁵⁰ (Fig. 5C and 6D). Maintaining the redox balance in C/CM4x decelerates the degradation of thylakoids resulting in a more efficient photosynthetic capacity (P_{net} and F_v/F_m) compared to C/CM2x, C/CC2x and C/CC4x after nutrient deficiency (Tables 2 and 3; Fig. 2, 3, 5A, 5C and 6D). Plastoglobuli are bound to thylakoids via their membranes. Studies have shown that plastoglobuli are involved in the formation and degradation of thylakoids during plant growth, development and senescence but also when plants are exposed to drought, high-light, N starvation or fungal infection^{46,51–53}. The reduced damage of the thylakoid membrane in C/CM4x would explain [the maintenance of the plastoglobuli numbers and the small increase in their size](#) due to the accumulation of catabolites formed by thylakoid degradation in their hydrophobic core compared to other scion/rootstock combinations^{54,55} (Tables 2 and 3; Fig. 2 and 3).

Rootstock tetraploidy improves the tolerance of 2x common clementine scions by maintaining the redox status and delaying ultrastructural changes and damage with a consequent improvement in photosynthetic capacity. However, as suggested by the similar impact of nutrient deficiency on C/CC2x and C/CC4x, rootstock tetraploidy does not automatically result in better tolerance of the photosynthetic properties of the scion.

Differences in tolerance to nutrient stress between scion/rootstock combinations may be explained by a better antioxidant system

Nutrient deprivation led to a modification of oxidative metabolism^{35,39,56}. Tolerance differences between scion/rootstock combinations may be related to differences in ROS production and/or antioxidant system efficiency. The enzymatic antioxidant system response differs according to plant species and the deficient minerals⁵⁶⁻⁶⁰. Enzymatic antioxidant systems in common clementine leaves differed depending on the rootstock genotypes (Fig. 6).

Nutrient deficiency impaired SOD activity in C/CC4x and C/CM4x (Fig. 6A). It was interesting to note that APX activity either increased or remained similar to the control in all scion/rootstock combinations (Fig. 6C) whereas CAT activity only increased in C/CM4x under nutrient deficiency (Fig. 6B). Concurrent CAT and APX activity is important for the elimination of H_2O_2 ⁶¹⁻⁶³. In C/CM2x, C/CC2x and C/CC4x, the low H_2O_2 and high MDA contents were due to increased $OH^\bullet$ formation (Fig. 6D and E). This $OH^\bullet$ is either directly formed by the addition of electrons to the $O_2^{\bullet -}$ not transformed into H_2O_2 by SOD and/or by the transformation of H_2O_2 via Fenton or Haber-Weiss reactions when the APX activity is insufficient to compensate for the low CAT activity. Conversely, in C/CM4x, the synergistic activity of CAT and APX maintains the MDA content in C/CM4x (Fig. 6B, C and D). As in their ungrafted counterparts, the increased enzymatic activity may explain the reduced ultrastructural damage and decrease in photosynthetic activity in C/CM4x in comparison with the other scion/rootstock combinations. The improvement in performance of the enzyme-based antioxidant system in the scion is due to the tetraploidization of the rootstock and the compatibility between rootstock and scion.

In conclusion, rootstock ploidy level had no effect on the structure of the common clementine scion leaves (except stoma density in Carrizo citrange) whereas it induced modifications in the ultrastructural components. The impact of prolonged nutrient deficiency on the structure, ultrastructure, physiology and biochemistry of the common clementine scion differed according to the variety and ploidy level of the rootstock. Among the four scion/rootstock combinations, common clementine grafted with 4x citrumelo 4475 rootstock (C/CM4x) was the most tolerant to nutrient deficiency as indicated by the limited changes in leaf cell structures and photosynthetic activity. The improved tolerance of common clementine grafted with 4x citrumelo 4475 rootstock may be related to a better antioxidant system. Tolerance to nutrient deficiency can therefore be improved by rootstock polyploidy but remains dependent on the rootstock

genotype. The next step of this study will be to test the impact of rootstock ploidy level on the quality and yield of clementine fruit under nutrient deficiency.

Materials And Methods

Plant material and experimental design

The experiment was carried out on the AREFLEC experimental station located in San Giuliano, Corsica (41° 47' 27"N and 09° 23' 40"E). 2x common clementine (*Citrus clementina* Hort. ex Tan; SRA 92) scion grafted onto one year seedlings of Carrizo citrange (*Citrus sinensis* L. Osb. × *Poncirus trifoliata* L. Raf.) and Citrumelo 4475 (*Citrus paradisi* L. Macf. × *Poncirus trifoliata* L. Raf.) 2x (C/CC2x and C/CM2x, respectively) and their 4x counterparts (C/CC4x and C/CM4x, respectively) were used as source materials. The ploidy status of six seedlings for each combination was first checked by flow 10 cytometry (Partec I, Germany) according to Froelicher et al.²¹. Clonal propagation by nucellar embryogenesis was checked by genotyping using SSR markers as described in Vieira et al.²².

The 24 selected scion/rootstock combinations were then grown under identical conditions in vermiculite with fertigation and water (1L/h) for three years in a tunnel greenhouse. The stock solution used for irrigation included: 20-5-10 NPK + 2MgO fertilizer + trace elements according to the recommendations of the French department of agriculture. Seedlings were divided into two blocks: one with reference fertigation (control plants) and the other with irrigation water (without nutrient inputs). A total of three plants of each scion/rootstock combination were randomized by fertigation level ($n = 3$). The fertigation solutions were prepared and applied with a metering pump. Before starting the experiment, the vermiculite was washed for 48 hours in order to eliminate any nutritional reserves in the pot.

According to a previous experiment of Oustric et al.²⁰, leaf and root samples were collected and physiological measurements made from May to December 2018 at two different times (days): 0 (D0: control plant) and 210 (D210) days after the start of nutritional deprivation. Measurements were made and samples taken from homogeneous plants comprising four branches with fully-expanded leaves developed under stress and control conditions.

Scanning electron microscopy (SEM)

Scanning electron microscopy measurements were carried out on three leaf pieces per scion/rootstock combination and fertigation level (typically 1 cm²) ($n = 3$) cut with a razor blade from mid-laminar areas at between 10:00 and 11:00 am. As described in Oustric et al.²⁰, leaves were then immediately fixed in cold (4 °C) 2.5% (v/v) glutaraldehyde in 0.1 M sodium cacodylate buffer at pH 7.2, rinsed in a 0.1 M cacodylate buffer at pH 7.2, dehydrated through a graded ethanol series (30%, 50%, 75%, 90% and 100%) and dried under CO₂ in an Emitech K850 critical point dryer (Quorum Technologies Ltd, Ashford, U.K.). Specimens were mounted on aluminum stubs with carbon double-sided adhesive disks, coated with

gold/palladium in a SC7640 sputter coater (Quorum Technologies Ltd, Newhaven, U.K.) and examined under a S-3400N scanning electron microscope (Hitachi High-Technologies Corporation, Tokyo, Japan) at an accelerating voltage of 5 kV.

Transmission electron microscopy (TEM)

Transmission electron microscopy measurements were carried out on five leaf pieces per scion/rootstock combination and fertigation level (typically 1 mm²) ($n = 5$) cut with a razor blade from mid-laminar areas at between 10:00 and 11:00 am. As described in Oustric et al.²⁰, leaves were immediately fixed in cold (4 °C) 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer at pH 7.2, rinsed in a 0.1 M cacodylate buffer at pH 7.2, post-fixed in cold (4 °C) 1% osmium tetroxide in the same buffer for 1 h, dehydrated through a graded ethanol series (70% and 100%) and propylene oxide, embedded in Spurr, and polymerized at 60 °C for 24 h. Ultra-thin sections (60–90 nm) were cut using a Power tome PC ultramicrotome (RMC Boeckeler, Tuscon, U.S.A.). Sections were placed on 200- and 300-mesh copper grids and stained with UranylLess (Delta Microscopies, France) and lead citrate. They were then examined using a Hitachi H-7650 (Hitachi High-Technologies Corporation, Tokyo, Japan) at an accelerating voltage of 80 kV.

Mineral content was measured on a pool of eight fully expanded leaves for the three plants per combination and fertigation level ($n = 3$) between 10:00 and 11:00 am. Fresh leaves were placed in a forced air oven at $65 \pm 10^\circ \text{C}$ overnight and then transferred into a desiccator for cooling. The dehydrated leaves were then sent to the CIRAD “Analyses des eaux, sols et végétaux service unit” at Montpellier (France) for analysis of macro- and micro-nutrients.

Leaf P, K, Ca, Mg and Na contents were measured using an Agilent 720 simultaneous ICP-OES after double calcination with silica removal by adding hydrofluoric acid.

The leaf total N content was evaluated after combustion using a Leco TruMac N determinator.

Measurements of gas exchange and chlorophyll a fluorescence

All measurements were made on three fully developed leaves for each of the three plants per combination and fertigation level ($n = 9$). A portable photosynthesis system (LI600) was used to measure the leaf net photosynthetic rate (P_{net}), stomatal conductance (g_s) and transpiration rate (E) at between 7:00 and 11:00 am. The carbon dioxide concentration (CO₂), airflow rate, light intensity and temperature of the leaf chamber were maintained at 380 µmol.mol⁻¹, 500 µmol.s⁻¹, 1400 µmol.m⁻².s⁻¹ and 25 °C, respectively.

Chlorophyll a fluorescence parameters were measured using an OS1p (Hansatech, Instruments Ltd) at between 9:00 and 11:00 am. Leaves were dark-acclimated for 30 min using special leaf clips. Chlorophyll a fluorescence was recorded after illumination with red actinic light (650nm, 3000 µmol photon.m⁻².s⁻¹)

for 1 s and this was used to calculate the maximum fluorescence [$F_v/F_m = (F_m - F_o)/F_m$]²³. Leaves were exposed to an actinic light to evaluate the current fluorescence yield (F_s) and the actual light-adapted fluorescence (F_m'). Formulas were applied to this data in order to determine the effective quantum yield of PSII $Y(II) = (F_m' - F_s)/F_m'$, the $Y(NO) = F_s/F_m$, the non-photochemical quenching coefficient [$Y(NPQ) = (F_s/F_m') - Y(NO)$]^{24,25}, and the electron transport rate through PSII [$ETR(II) = Y(II) \times PAR \times 0.5 \times 0.84$]²⁶. The ETR/P_{net} ratio was calculated to estimate the use of electrons in other processes unrelated to the photosynthetic CO₂ assimilation rate.

Determination of oxidative stress and antioxidant levels

Biochemical analyses were performed on three samples for each scion/rootstock combination, i.e. one per tree, obtained by pooling eight fully-expanded leaves ($n = 3$) collected between 10:00 and 11:00 am and immediately immersed in liquid nitrogen and stored at -80 °C. Immediately prior to biochemical analysis, each leaf and root sample was ground to a fine powder in liquid nitrogen.

Malondialdehyde (MDA) and antioxidant enzyme activities (SOD, CAT, and APX) were assayed as defined by Santini et al.²⁷

Hydrogen peroxide (H₂O₂) was assayed using the PeroxiDetect kit (Sigma-Aldrich). This technique is based on the oxidation of ferrous (Fe²⁺) to ferric ions (Fe³⁺) by hydroperoxides which react with xylenol orange ("3,3'-bis[N,N-bis(carboxymethyl)aminomethyl] o-cresolsulfonephthalein, sodium salt") to form a blue complex visible at 560 nm.

Proline content was measured as described by Oustric et al.²⁸

A V-630 spectrophotometer was used for all measurements (Jasco Inc., Tokyo, Japan).

Statistical analyses

All statistical measurements were performed with R statistical software (v.2.12.1) (<http://www.R-project.org>) and the Rcmdr package. The qualitative factors studied were sampling date (D0 and D210 after nutrient deficiency), the common clementine scion grafted onto rootstocks subjected to nutrient stress (C/CC and C/CM) and the ploidy level of nutrient stressed rootstocks (C/CC2x, C/CC4x, C/CM2x and C/CM4x). The influence of these three factors was analyzed using a two-way ANOVA followed by LSD test at $p < 0.05$.

The microscopic data obtained on leaves of common clementine scion grafted onto the various rootstocks at D0 (control) and D210 of nutrient deficiency were analyzed by heatmaps generated by Heatmap.2 function of the gplot package 3.0.1 for Rstudio (v.1.3.1093) (<https://rstudio.com>).

Declarations

Acknowledgements

This work was funded by the “Collectivité de Corse” as part of the “Innov’agrumes” research project (FEDER). We thank Jean-Claude Ribaut for hosting this study at the AREFLEC experimental station, and Gilles Paolacci and Paul Martin for installing and monitoring the fertigation system in the greenhouse.
