ABSTRACT

Brown algae are one of the most developmentally complex groups within the eukaryotes. As in many land plants and animals, their main body axis is established early in development, when the initial cell gives rise to two daughter cells that have apical and basal identities, equivalent to shoot and root identities in land plants, respectively. We show here that mutations in the *Ectocarpus DISTAG* (*DIS*) gene lead to loss of basal structures during both the gametophyte and the sporophyte generations. Several

abnormalities were observed in the germinating initial cell in *dis* mutants including increased cell size, disorganisation of the Golgi apparatus, disruption of the microtubule network and aberrant positioning of the nucleus. *DIS* encodes a TBCCd1 protein, which has a role in internal cell organization in animals, *Chlamydomonas* and trypanosomes. Our study highlights the key role of subcellular events within the germinating initial cell in the determination of apical/basal cell identities in a brown alga, and emphasizes the remarkable functional conservation of TBCCd1 in regulating internal cell organization across extremely distant eukaryotic groups.

SHORT TITLE

Basal cell fate determination in *Ectocarpus.*

ONE SENTENCE SUMMARY

Mutations in the *Ectocarpus DISTAG* gene, which encodes a TBCCd1 protein, disrupt the subcellular architecture in the germinating initial cell leading to loss of all basal structures from the developing alga.

INTRODUCTION

Events in the zygote leading up to and including the first cell division play a key role in the developmental patterning of multicellular organisms. In many plants and animals, asymmetric division of the zygote establishes the principal body axis of the early embryo, representing the first major patterning event during embryogenesis (Gönczy and Rose, 2005; Ueda and Laux, 2012). In land plants, the first cell division usually coincides with the establishment of apical and basal cell identities (Ueda and Laux, 2012) (but note that some fern gametophytes have tripolar germination patterns, Schneider, 2013). In *Arabidopsis* the asymmetrical division of the zygote is associated with a number of cellular events including movement of the nucleus to the apex of the cell, repositioning of other major organelles, formation of a large vacuole in the basal part of the cell and reorganisation of the microtubules into transverse cortical arrays associated with cell

outgrowth in the apical direction (Jeong et al., 2011a; Kimata et al., 2016; Lau et al., 2012). The establishment of the apical-basal axis in *Arabidopsis* has been shown to be controlled by a complex genetic network involving both auxin-dependent and auxin-independent pathways (Lau et al., 2012). The auxin-dependent network involves the transcription factor MONOPTEROS/AUXIN RESPONSE FACTOR 5, the auxin response inhibitor BODENLOS/INDOLE-3-ACETIC-ACID 12 and the auxin efflux carrier PIN-FORMED 7, whereas the auxin-independent pathway involves EMBRYO SURROUNDING FACTOR 1 (ESF1), the receptor-like cytosolic kinase SHORT SUSPENSOR, the MAP kinase kinase YODA, the MAP kinases MPK3 and MPK6 and several transcription factors including GROUNDED/RKD4 and WOX2 (Jeong et al., 2011b; Waki et al., 2011; Costa et al., 2014; Lau et al., 2012; Rademacher et al., 2012). However, it is not yet clear how these genetic networks implement the cellular events that underlie the formation of the apical-basal axis and the establishment of apical and basal cell identities.

The brown algae have evolved complex multicellularity independently of land plants but the two lineages share several key developmental characteristics such as the importance of the establishment of the apical/basal axis during development, extensive post-embryonic developmental patterning and developmental programs constrained by the absence of cell migration. The apical and basal structures of brown algae and land plants can also be considered to be analogous, with the basal systems of brown algae being functionally equivalent to rooting structures in land plants. In both lineages, the basal systems are composed of tip-growing filamentous rhizoid cells that extend into the substrate or air/water surrounding the plant and are used for anchoring (Jones and Dolan, 2012). In both brown algae and flowering plants apical/basal polarity is usually determined very early, before the first cell division (Fritsch, 1935). However, this process may be less complex in brown algae, because the development of initial cells (e.g. the zygote) does not occur within maternal tissues. Consequently, axis formation is expected to occur in a cell autonomous manner (but see (Whitaker, 1931) and not to be influenced by signals emitted by nearby parental cells (Costa et al., 2014).

84   The brown alga *Fucus* has been used for many years as a model system to study apical-
85   basal axis formation during embryogenesis (e.g. Coelho et al., 2002; Brownlee and
86   Bouget, 1998; Kropf et al., 1988). As in land plants, the zygote cell divides
87   asymmetrically to establish the apical-basal axis (Bouget et al., 1998; Goodner and
88   Quatrano, 1993). The two products of this division go on to produce the apical and basal
89   systems of the alga, the thallus and the rhizoid, respectively (Brownlee and Bouget,
90   1998). The establishment of the apical-basal axis in *Fucus* has been studied in detail at
91   the cellular level and has been shown to involve position dependent information from the
92   cell wall (Berger et al., 1994). Apoplastic diffusible gradients appear also to be involved
93   in pattern formation in the multicellular *Fucus* embryo (Bouget et al., 1998).

94   Whilst the large zygote and the external fertilisation process (fusion of male and
95   female gametes released from the parent thallus) of *Fucus* makes it well adapted for the
96   study of the cell biology of axis formation, this genus is not amenable to genetic
97   approaches and, consequently, the genetic networks that control apical-basal axis
98   formation have not been characterized in the brown alga lineage. Recently, the
99   filamentous alga *Ectocarpus* sp. has emerged as a genetic model for the brown algae
100   (Coelho et al., 2012c; Cock et al., 2014). A high-quality genome sequence is available for
101   this species (Cock et al., 2010; Cormier et al., 2017), together with extensive
102   transcriptomic data (e.g. Lipinska et al., 2015; Luthringer et al., 2015) and genetic tools
103   including a dense genetic map (Heesch et al., 2010; Avia et al., 2017). Genetic
104   transformation is not yet possible but gene knockdown using RNA interference has been
105   demonstrated (Macaisne et al., 2017). These various tools were employed in a recent
106   study that was the first to identify a brown algal developmental gene using a forward
107   genetic approach (Macaisne et al., 2017).

108   *Ectocarpus* has a complex life cycle involving alternation between multicellular
109   sporophyte and gametophyte generations (Coelho et al., 2012c; Peters et al., 2008)
110   (Supplemental Figure 1). Unlike land plants, both the sporophyte and the gametophyte
111   are derived from single cells, which are released into the seawater medium (gametes and
112   meio-spores, respectively) greatly facilitating the analysis of early events during
113   development. This characteristic also means that any parental influence on developmental

4

114 processes is essentially limited to information provided to the propagules before their
115 release (but see also Arun et al., 2013).

116   Both the gametophyte and the sporophyte possess an apical-basal axis and clearly
117 defined apical and basal filamentous systems (Coelho et al., 2011; Peters et al., 2008). In
118 the gametophyte, the basal system consists of rhizoids and the apical system is composed
119 of upright filaments that bear the gametangia. In the sporophyte, the basal system is more
120 extensive, consisting of a network of firmly attached basal filaments, whereas the apical
121 system resembles that of the gametophyte, consisting of branched upright filaments that
122 bear the sexual structures. The general similarities between the gametophyte and
123 sporophyte generations, in terms of their size and overall morphologies, make *Ectocarpus*
124 an ideal system to investigate how two distinct developmental programs can be deployed
125 from the same genome.

126   In this study, we report the identification of the *DISTAG* (*DIS*) locus, which is required
127 for the formation of basal structures during both the sporophyte and gametophyte
128 generations of the *Ectocarpus* life cycle. *DIS* encodes a Tubulin Binding Co-factor C
129 (TBCC) domain protein of the TBCCd1 class. Mutations in the *Ectocarpus DIS* gene are
130 associated with several modifications at the initial cell stage: disorganisation of the Golgi
131 apparatus, increased cell size, disruption of the pattern of the microtubule network and
132 aberrant positioning of the nucleus. *dis* mutants therefore link subcellular events within
133 the initial cell with the acquisition of apical/basal cell identities. The phenotypes of *dis*
134 mutants also confirm that the basal filament system of the sporophyte is developmentally
135 equivalent to the rhizoid of the gametophyte generation, providing insight into the
136 evolutionary events that led to the emergence of the sporophyte and gametophyte
137 developmental programs in this species.

138   RESULTS

139   ***dis* mutants lack a basal system**

140   During the *Ectocarpus* gametophyte generation the apical/basal axis is established in
141 the initial cell, prior to the first cell division. The two cells derived from the division of

142   the initial cell grow, in the form of two germ tubes, to establish a rhizoid (basal, root-like

143   organ) and a filamentous thallus (apical, shoot-like organ) (Figure 1). A UV mutagenesis

144   screen identified two mutant strains (Ec722 and Ec799, Supplemental Table 1;

145   Supplemental Figure 2) that failed to develop any of the basal structures normally

146   observed in the wild type gametophyte generation, i.e., the initial cells of the mutants

147   immediately developed as apical upright filaments.

148   During the early development of the wild type sporophyte generation, establishment of

149   apical structures is delayed and an extensive system of prostrate filaments consisting of

150   round cells is formed before the apical thallus filaments develop (Peters et al., 2008;

151   Figure 1). Several observations indicate that this basal network of prostrate filaments is

152   equivalent to the basal system of the gametophyte generation, represented by the rhizoid:

153   1) both structures develop at the base of the alga (in contact with the substratum), 2) both

154   structures serve an anchoring function and 3) in sporophytes carrying the *immediate*

155   *upright (imm)* mutation the system of prostrate filaments is homeotically replaced by a

156   rhizoid similar to that of the gametophyte (Peters et al., 2008; Macaisne et al., 2017).

157   The sporophyte generations of the Ec722 and Ec799 mutants failed to produce a

158   network of prostrate filaments and therefore also lacked basal structures (Figure 1). The

159   establishment of reproductive structures on apical systems was unaffected in both

160   generations, and the mutants were fully fertile as both gametophytes and sporophytes

161   (Figure 1).

162   The absence of a basal system significantly affected the capacity of the mutants to

163   adhere to the substratum (Figure 2) and consequently Ec722 and Ec799 were named

164   *distag-1* (*dis-1*) and *distag-2* (*dis-2*), respectively ('distag' means detached in the Breton

165   language). The loss of basal systems during both the gametophyte and sporophyte

166   generation in *dis* mutants is consistent with these two systems (rhizoids and prostrate

167   filaments, respectively) being developmentally equivalent between the two generations.

168   Developmental equivalence between the basal systems of the two generations was further

169   supported by the observation that when *dis-1 imm* double mutants were constructed these

170   lacked the rhizoid that replaces the prostrate filaments in the *imm* mutant (Figure 2).

6

171   Analysis of a segregating family generated from a cross between *dis IMM* and *DIS imm*

172   parents indicated that *DIS* is epistatic to *IMM* (Supplemental Table 2).

173   In wild type *Ectocarpus*, secondary rhizoids are produced from the apical system cells

174   at a late stage of development (Peters et al., 2008) (Figure 1). These rhizoids can be

175   considered to be analogous to the adventitious roots produced from the stems of some

176   land plants (Atkinson et al., 2014). The *dis-1* and *dis-2* mutants failed to produce

177   secondary rhizoids during both the sporophyte and the gametophyte generations. Hence,

178   production of all basal structures, both primary and secondary, was blocked in these

179   mutants.

180   In fucoid brown algae, the apical system (the thallus), responds to damage by

181   producing rhizoids (e.g. (Bouget et al., 1998), and we observed a similar phenomenon in

182   wild type *Ectocarpus*. In contrast to the wild type, wounded apical filaments of the *dis*

183   mutants failed to regenerate rhizoids, and instead produced new cylindrical apical

184   filament cells (Figure 2; Supplemental Figure 3). Taken together, our results indicate that

185   basal system formation fails to occur, at all developmental stages, in the absence of a

186   functional *DIS* gene product.

187   One consequence of the loss of basal structures in the *dis* mutants is that the

188   sporophyte and gametophyte generations are more similar than in the wild type because

189   in both cases the vegetative thalli consist uniquely of upright filaments made up of

190   cylindrical cells. Despite this resemblance, the sporophyte and gametophyte generations

191   of the *dis* mutants retained generation-specific features. First, morphometric

192   measurements showed that the length and width of the filament cylindrical cells and the

193   angle at which secondary upright filaments branch off from primary filaments

194   statistically distinguished sporophyte from gametophyte thalli in both wild type and *dis*

195   mutant strains. In contrast, no significant differences were detected when these

196   parameters were compared between the same generation of wild type and mutant strains

197   (Supplemental Table 3). Second, at maturity *dis* gametophytes produced plurilocular

198   gametangia, which contained gametes that were able to fuse with gametes of the opposite

199   sex to produce zygotes. The sporophyte generation of the *dis* mutants, on the other hand,

200   produced plurilocular sporangia containing spores (incapable of fusion) and unilocular

201   sporangia with haploid, meiosis-derived meio-spores. Finally, the expression patterns of

202   generation-specific marker genes (Peters et al., 2008) were consistent with assigned life

203   cycle generations in both wild type and *dis* individuals (Supplemental Figure 4).

204   **Analysis of the *dis* transcriptome**

205   To further characterize the Dis[-] phenotype, an RNA-seq approach was employed to

206   study gene expression in the *dis-1* mutant compared with wild type basal and apical

207   tissues (Supplemental Table 4). Consistent with the fact that *dis* has lost the ability to

208   produce a basal system and is composed exclusively of apical system cells, analysis of

209   *dis* transcriptional profiles indicated that they were more similar to apical than to basal

210   transcriptomes of the wild type strain (Figure 3A, 3B; Supplemental Figure 5).

211   Several analyses were carried out to characterize the set of genes that were

212   differentially expressed in the three tissues analysed. These included an analysis of the

213   putative functions of clusters of genes with shared patterns of regulation (Supplemental

214   Table 5 and 6), an analysis of the 200 most differentially expressed genes (100 most up-

215   and 100 most down-regulated) in these comparisons (Supplemental Table 7 and 8), an

216   analysis of the differentially regulated genes that coded for proteins with putative signal

217   peptides (representing putative secreted proteins, Supplemental Table 9 and 10) and a

218   KEGG pathway analysis (Supplemental Table 11). Global patterns in the changes in gene

219   expression were analysed using a set of manually assigned functional categories (based

220   on the functional categories used in Tarver et al. (2015). GO term enrichment analysis

221   (Blast2Go; Conesa and Götz, 2008) and KEGG analysis were then used to provide more

222   detailed information about the processes and pathways affected. The relative frequency of

223   the manually assigned functional categories was visualized using a word cloud (Figure

224   3C). Note that about half of the genes in the transcriptome datasets were of unknown

225   function, and these were excluded from our analysis.

226   **Putative basal and apical system effector genes**. The gene cluster analysis focused

227   on genes that were either up- or downregulated in both the *dis-1* mutant and wild type

228   apical tissues compared to wild type basal tissues (Figure 3A, 3B; Supplemental Table 5).

229   The aim of this approach was to identify potential basal and apical system effector genes.

230   The set of genes that was upregulated in *dis* and the wild type apical system compared to

231   the wild type basal system (potential apical system effectors) were enriched in the GO

232   categories 'kinase activity', 'protein modification', 'cell differentiation' and 'cell

233   communication' (Fisher's exact test, $p<0.05$) while the genes that were downregulated in

234   both *dis-1* and the apical system compared to the basal system (potential basal system

235   effectors) were enriched in categories related to 'transcriptional activity', 'signal

236   transduction' and 'extracellular' or 'membrane-located processes' (Supplemental Table

237   6). Accordingly, the assignment of basal and apical effector genes to manually curated

238   functional groups highlighted an important proportion of genes coding for proteins

239   putatively involved in membrane functions and transport, cell wall biosynthesis and

240   modification, vesicle trafficking, adhesion, cell regulation and signalling (Figure 3C

241   upper panel, Supplemental Table 12).

242   **Top-200 most differentially regulated genes.** GO term enrichment analysis of the

243   200 most differentially regulated genes in the *dis-1* mutant compared with wild type basal

244   and apical systems highlighted a range of GO term categories (Supplemental Table 8),

245   but there was a particular abundance of genes with functions related to 'membrane',

246   'oxidation-reduction process' and 'carbohydrate metabolic processes'. The cellular

247   components highlighted by the GO term analyses were 'membrane' and 'extracellular

248   region'. Manual assignment to functional categories revealed that the common functional

249   groups represented within this set of genes included cell wall biosynthesis and

250   organization, membrane function and transport, cell regulation and signalling, adhesion,

251   vesicle transport and cytoskeleton (Figure 3C middle panel, Supplemental Table 12).

252   **Secreted proteins**. The set of differentially expressed genes that were predicted to

253   encode secreted proteins were analysed in detail because the phenotypes of the *dis*

254   mutants are associated with disruption of the Golgi apparatus. Interestingly, a

255   disproportionate number of genes coding for proteins with a putative signal peptide were

256   present in the pool of genes that were differentially regulated in *dis* versus wild type basal

257   system (Fisher test, p-value=0.00002877 and p-value=0.01992 for up and downregulated

258   genes, respectively; Supplementary Table 4). Analysis of the GO term associated with

259   these genes indicated enrichment for range of GO categories including carbohydrate
260   transport, transmembrane transport, extracellular components, integral components of
261   membrane, transmembrane signalling and Golgi associated vesicles (Supplemental Table
262   10). The most commonly represented manually annotated functional categories
263   represented within this dataset included, as above, cell wall, adhesion, extracellular
264   processes, membrane function and transporters, cytoskeleton, and cellular regulation and
265   signalling (Figure 3C lower panel).

266   **KEGG analysis**. Analysis of the assignment of the differentially expressed genes to
267   KEGG pathways (Xie et al., 2011) revealed a number of processes that were
268   differentially regulated in *dis* versus wild type samples. Pathways involved in interactions
269   with the extracellular-matrix, protein processing in the endoplasmic reticulum and protein
270   export were upregulated in the *dis-1* mutant compared with the wild type basal system,
271   whereas signalling pathways and protein processing in the endoplasmic reticulum were
272   downregulated (Supplemental Figure 7; Supplemental Table 11).

273   Taken together, comparison of the *dis-1* transcriptome with wild type basal and apical
274   tissues suggested that carbohydrate/cell wall-related processes, membrane transport,
275   cellular signalling and secretory activity may be affected in *dis* mutants.

276   Note that transcript abundance was also measured using an independent method (RT-
277   qPCR) for 12 of the differentially regulated genes to verify that the differential
278   expression patterns observed were robust (Supplemental Figure 6). Globally, the results
279   of the RT-qPCR analysis confirmed those obtained based on the RNA-seq data
280   (Spearman's correlation R^2=0.619, p-value = 0.0012).

281   **Loss of bipolar germination from the initial cell in *dis* mutants**

282   The vast majority of initial cells of both the sporophyte and gametophyte generations
283   of the *dis* mutants produced a single germ tube rather than the two germ tubes normally
284   observed with wild type strains (Peters et al., 2008). This phenotype was observed more
285   consistently with the *dis-2* mutant than with the *dis-1* mutant (85% and 95% for *dis-1* and
286   *dis-2* sporophytes respectively, n=591; 82% and 95% for *dis-1* and *dis-2* gametophytes

287 respectively, n=54) (Figure 2). We also noted that, whilst the *dis-2* mutant completely
288 failed to produce a second germ tube, a proportion of *dis-1* individuals (65%, n=235)
289 produced one or more enlarged and abnormally shaped cells at the end where the second
290 germ tube would normally emerge, possibly corresponding to an aborted basal system
291 (Figure 2).

292   **Genetic analysis and identification of the *DIS* gene**

293   Sporophytes can be propagated asexually through the production of mito-spores
294 (Figure 1). The Dis⁻ mutant phenotype was stable through 30 rounds of asexual
295 generations via mito-spores.

296   A male *dis-1* gametophyte (Ec722) was crossed with an outcrossing wild type female
297 gametophyte of the strain Ec568 (Coelho et al., 2011; Peters et al., 2008) (Supplemental
298 Table 1, Supplemental Figure 2). The resulting sporophyte (Ec653) exhibited a wild type
299 pattern of development indicating that the *dis-1* mutation was recessive. A segregating
300 population of 200 individuals derived from this cross consisted of 92 and 108
301 phenotypically wild type and mutant individuals, respectively, consistent with a 1:1
302 segregation ratio and Mendelian inheritance of a single-locus recessive mutation (Chi-
303 square test = 1.28, df = 1, p-value = 0.257). A female individual from this progeny that
304 carried the *dis-1* mutation was crossed with a male gametophyte of the *dis-2* strain
305 (Ec799). The resulting sporophytes (Ec808, Ec809) exhibited a Dis⁻ phenotype indicating
306 that the two mutations *dis-1* and *dis-2* were allelic.

307   A cloning-by-sequencing approach (Schneeberger et al., 2009) identified a candidate
308 locus on chromosome 05 for the location of the mutation in the *dis-1* mutant (Figure 4A)
309 and sequencing of this genomic region identified a single nucleotide mutation at position
310 3330523 that was present in the *dis-1* mutant (Ec722) but absent from the Ec32 and
311 Ec568 wild type strains (Figure 4B). This mutation was located in intron 15 of the gene
312 Ec-05_001860. A cleaved amplified polymorphic sequence (CAPS) marker, developed
313 based on the candidate causal mutation, showed absolute co-segregation of this mutation
314 with the Dis⁻ phenotype in 265 individuals of the segregating family derived from
315 sporophyte Ec653. Re-sequencing of the Ec-05_001860 gene in the *dis-2* mutant

11

316 identified a point mutation in exon 13 that results in the introduction of a stop codon into

317 the coding region of the gene (Figure 4B). Taken together, these analyses provide strong

318 evidence that Ec-05_001860 corresponded to the *DIS* gene.

319 A protocol for genetic transformation does not exist for *Ectocarpus* (or for any other

320 brown alga), but injection of double stranded RNA into zygotes of the brown alga *Fucus*

321 has been shown to induce an RNA interference (RNAi) response, leading to knockdown

322 of target gene expression (Farnham et al., 2013). We have recently adapted this *Fucus*

323 RNAi protocol for *Ectocarpus,* using synthetic siRNA molecules instead of long double

324 stranded RNA molecules and a lipofectant specifically adapted for dsRNA delivery to

325 introduce the siRNAs into the cell rather than the microinjection procedure used for

326 *Fucus* (Macaisne et al., 2017).

327 Following simultaneous introduction of three siRNA molecules targeting the *DIS* gene,

328 a small proportion (about 2.5%) of the parthenogenetic gametes exhibited a pattern of

329 development that closely resembled the phenotypes of the *dis* mutants (Figure 4C); the

330 gametes emitted a germ tube in a unipolar manner. Germination gave rise to an upright

331 filament consisting of the cylindrical cells typical of the apical system. The gametes that

332 showed unipolar germination occasionally produced an aborted second germ tube with an

333 abnormally shaped cell similar to the enlarged and abnormally shaped cells that are

334 sometimes produced by *dis-1* mutants. This phenotype was not observed in the control

335 treatments, where initial cells were incubated with siRNA molecules directed against

336 another *Ectocarpus* sp. gene (Ec-13_001890). These observations indicated that RNA-

337 interference-induced knockdown of *DIS* gene expression had the same developmental

338 consequences as the *dis* mutation in a proportion of the treated individuals, further

339 confirming that Ec-05_001860 corresponds to the *DIS* gene.

340 **Expression pattern of the *DIS* gene during the life cycle**

341 RT-qPCR analysis indicated that, as expected, *DIS* transcript abundance was

342 significantly reduced in both *dis-1* and *dis-2* mutants (Supplemental Figure 8).

343   We used RNA-seq to assay the abundance of the *DIS* transcript throughout the life

344   cycle of *Ectocarpus*. Specifically, we compared the expression of *DIS* at several stages of

345   the ontogeny of the gametophyte and in several tissues of the sporophyte generation

346   (Supplemental Figure 1B). This analysis indicated that transcription of *DIS* was

347   upregulated in the basal system compared with the apical upright system during the

348   sporophyte generation (pairwise analysis between apical system and basal system,

349   FC=1.9; p_{adj}= 7.66E^{-06}). The *DIS* transcript was detected at low abundance during the

350   gametophyte generation (which consists predominantly of apical filament cells), similar

351   to the level detected in the apical system of the sporophyte (Supplemental Figure 8).

352   Taken together, the expression pattern of *DIS* during the life cycle of *Ectocarpus* is

353   consistent with a role in the regulation of the basal system, both during the gametophyte

354   and the sporophyte generations.

355   **_DIS_ encodes the conserved protein TBCCd1**

356   The *DIS* gene is predicted to encode a 774-amino acid protein with a tubulin binding

357   cofactor C (TBCC) domain (accession PF07986 in Pfam database; Supplemental Table

358   13). Three classes of TBCC proteins have been described in other eukaryotic lineages:

359   canonical TBCC, retinitis pigmentosa protein 2 (RP2) and TBCCd1. Phylogenetic

360   analysis indicated that *DIS* encodes a TBCCd1 protein (Figure 4D; Supplemental Figure

361   9; Supplemental Table 14). *DIS* is the only TBCCd1-encoding gene in the *Ectocarpus*

362   genome. Note that the stop codon in *dis-2* is located within the region encoding the

363   TBCC domain (Figure 4B).

364   Canonical TBCC functions together with several other tubulin cofactors/chaperones in

365   αβ-tubulin assembly and therefore plays a key role in microtubule dynamics (Tian et al.,

366   1996; Nithianantham et al., 2015). RP2 is also thought to be involved in microtubule

367   assembly but the role TBCCd1 is less clear. Phenotypic analyses have shown that

368   TBCCd1 plays an important role in positioning organelles within the cell in diverse

369   organisms (Feldman and Marshall, 2009; André et al., 2013) but the molecular

370   mechanism through which this protein acts is unclear and may not involve direct effects

371   on microtubule dynamics (Goncalves et al., 2010). These previous studies prompted us to

372   compare intracellular features of germinating *dis* initial cells with those of the wild type.

373   **No defects in flagella structure and function were detected in *dis* mutants**

374   *Chlamydomonas* mutants affected in the *ASQ2* gene (which encodes a TBCCd1

375   protein) have a variable number of flagella (Feldman and Marshall, 2009). In contrast, we

376   observed no variation in flagella number in *dis* mutant individuals and both the posterior

377   and the anterior flagella of *dis* gametes were morphologically similar to the wild type

378   equivalents and were positioned normally, being inserted asymmetrically on the "ventral"

379   side, close to the eyespot (Maier, 1997; Supplemental Table 15). *dis* gametes exhibited no

380   abnormal swimming behaviour that might have been indicative of loss of flagella

381   functionality; both wild type and *dis* gametes were positively phototactic (Supplemental

382   Table 15). Moreover, male gametes of *dis* and wild type strains showed no difference in

383   fertilization success, evidence that the former can swim towards female gametes in

384   response to pheromone release as efficiently as wild type gametes (Supplemental Table

385   15). In summary, we did not find any evidence that DIS is required for flagella

386   functionality.

387   **Initial cells of *dis* mutants exhibit increased cell size, modified Golgi architecture,**

388   **abnormal positioning of the nucleus and modification of the microtubule network**

389   The germinating initial cells of *dis* mutants were significantly larger than wild type

390   initial cells (mean areas of 53.9 µm^2, 54.1 µm^2 and 32.0 µm^2 for *dis-1*, *dis-2* and wild

391   type, respectively; Supplemental Table 15; Figure 5D) and analysis of transmission

392   electron microscopy (TEM) images indicated an unusually abundant trans Golgi network

393   in the initial cells of *dis* mutants, suggesting a perturbation of secretory activity (Figure

394   5A-F). Moreover, Golgi cisternae of *dis-1* and *dis-2* cells were significantly shorter than

395   those of the wild type (Wilcoxon test, p-value=1.22e^{-13}; Figure 5H). A similar phenotype

396   has been observed in TBCCd1-depleted human cells, which are enlarged and exhibit a

397   disorganized Golgi (Goncalves et al., 2010). The cellular phenotype of the *dis* mutants is

398   therefore consistent with TBCCd1 having a conserved role in maintaining the structural

14

399 integrity of the Golgi during early development across extremely distant eukaryotic
400 groups. Note that depletion of the tubulin binding co-factor TBCE also causes
401 disorganisation and fragmentation of the Golgi (Haase and Rabouille, 2015).

402   The microtubule network plays an important role in the positioning of cellular
403 organelles and has been implicated in the organisation and positioning of the Golgi
404 apparatus close to the nuclei (reviewed in Rios and Bornens, 2003). We therefore
405 investigated whether the microtubule network was altered in *dis* mutants. In wild type
406 initial cells, a well organised interphase microtubule network was visible during initial
407 cell germination. Microtubules nucleated from the pole opposite the first germination
408 tube and microtubule bundles were gently curved and oriented parallel to the germination
409 axis towards the germination pole (Figure 6A, B; Supplemental Figure 10). In *dis* mutant
410 cells, microtubule bundles were more abundant compared with the wild type (Figure 6;
411 Wilcoxon test, p=0.000156 and p=0.0069 for wild type versus *dis-1* and wild type versus
412 *dis-2* comparisons, respectively) and the architecture of the microtubule network was
413 disturbed. *dis* mutant microtubules were organised in wavy bundles with a criss-cross
414 pattern (Figure 6A, B; Supplemental Figure 10). The perturbations of the microtubule
415 architecture were only observed in the germinating initial cell, before the first cell
416 division. No abnormalities of the microtubule network were detected in *dis* mutant
417 filament cells at or after the two-cell stage, compared with wild type cells (Figure 6C).
418 Cells of wild type and *dis* 15 day old germlings exhibited similar microtubule networks
419 with bundles of a variety of thicknesses.

420   In addition to the above-mentioned flagellar phenotype, the *Chlamydomonas asq2*
421 mutant exhibits defects in centriole positioning and number (Feldman and Marshall,
422 2009). We examined two aspects of centriole positioning in the *Ectocarpus dis* mutants:
423 the degree with which centrioles were associated with the nucleus and the positioning of
424 the associated centriole and nucleus with respect to the germination axis. Regarding the
425 first aspect, centrioles were positioned close to the nuclei in both wild type and *dis*
426 mutant cells and there was no evidence of detachment of centrioles from the nuclear
427 envelope in *dis* mutants (Figure 5A-C). In contrast, we detected marked differences
428 between wild type and *dis* mutant cells with respect to the position of the centrioles in

429 relation to the germination pole. In wild type cells, centrioles (which co-localise with
430 microtubule nucleating sites, Figure 6E) were located close to the nucleus on the side
431 opposite the germination pole ('distal'), whereas in *dis* mutant cells, we observed
432 microtubule nucleation both laterally and on the proximate side of the nucleus (Figure
433 6F).

434 More than 200 *dis* mutant germlings were inspected at the two-cell stage to determine
435 whether the aberrant positioning of microtubule nucleation sites in germinating initial
436 cells leads to defects in the plane of cell division when these cells divides. This analysis
437 failed to detect any individuals showing signs of aberrant patterns of cell division, i.e.
438 there were no individuals in which the new septum was laid down obliquely, in a division
439 plane that was not perpendicular to the growth axis.

440 We also analysed the position of the nucleus within the germinating cell. In the
441 majority of wild type germinating initial cells the nucleus was positioned near the pole
442 opposite the first germination tube (Figure 6E). In contrast, the majority of the nuclei in
443 *dis-1* and *dis-2* initial cells were positioned centrally and in up to 30% of the cells the
444 nucleus was located at the germinating end, a configuration that was only observed very
445 rarely (about 2%) in wild type germinating initial cells (Figure 6E, F). Analysis of
446 individuals from the two-cell stage onwards did not detect any aberrations in the
447 positioning of the nuclei in *dis* mutants compared to the wild type (Wilcoxon test, p-
448 value=0.837 and P=0.207 for wild type vs *dis-1* and wild type vs *dis-2* respectively),
449 indicating that the phenotype observed in initial cells is limited to that stage of
450 development (Figure 6E).

451 Taken together, these analyses indicate that loss of the DIS protein leads to several
452 defects in subcellular architecture of the initial cell and that these defects are associated
453 with alterations in the microtubule network.

454 To further examine the role of microtubules during early development of *Ectocarpus*
455 initial cells, we analysed the effect of drugs that disrupt both microtubule polymerisation
456 and depolymerisation (although note that the increased number of microtubule bundles in
457 *dis* mutants is more consistent with a depolymerisation defect). Oryzalin, which induces

16

458   microtubule depolymerisation, significantly inhibited elongation of wild type initial cells

459   and delayed the first cell division but did not result in perturbations of the microtubule

460   network resembling those observed in the *dis* mutants (Supplemental Figure 11;

461   Supplemental Table 16). Furthermore, oryzalin treatment did not lead to aberrant

462   positioning of the nuclei, compared with wild type untreated control cells (Wilcoxon test,

463   W= 101.5, p-value = 0.3818, Supplemental Figure 11). Similarly, treatment of wild type

464   initial cells with taxol, a microtubule stabilizing drug, inhibited germination and cell

465   division but did not produce a cellular phenotype similar to that of the *dis* mutants. Taxol

466   treated cells had thick microtubule bundles that were mostly oriented parallel to the cell

467   membrane (Supplemental Figure 10, 11). This pattern differed from those of both

468   untreated wild type cells and *dis* cells. Taxol treatment did not have any significant effect

469   on the position of the nucleus in germinating cells (Wilcoxon test, W= 95, p-

470   value=0.1978, Supplemental Figure 11D).

471   The lack of any detectable effect of pharmacological perturbation of the microtubule

472   network on the positioning of the nucleus within the initial cell suggests that alternative

473   cytoskeletal components, such as actin filaments, may be involved in positioning the

474   nucleus, as observed in plant root hair cells (Ketelaar et al., 2002).

475   Brefeldin A (BFA) has been shown to disrupt the Golgi and to inhibit polarisation of

476   the germinating *Fucus* embryo (Bisgrove and Kropf, 2001; Hable and Kropf, 1998).

477   Treatment of *Ectocarpus* sp. initial cells for 24h with BFA weakened the cell wall

478   (leading to the release of cytosolic material) and inhibited cell elongation, but did not

479   reproduce the Dis⁻ phenotype (Supplemental Table 16, Supplemental Figure 11).

480   Taken together, the results of these pharmacological experiments suggest that the

481   phenotypes associated with the *dis* mutations are not simply due to defects in microtubule

482   polymerisation or depolymerisation nor to an overall deficiency in secretion.

483   ## DISCUSSION

484   **DIS is required for the establishment of basal structures in *Ectocarpus***

17

Analysis of the phenotypes of the two *dis* mutants described in this study indicated that the *DIS* gene is required for the development of basal structures throughout the *Ectocarpus* life cycle. In wild type *Ectocarpus* gametophytes, the initial cell divides asymmetrically to produce two cells with apical and basal identities. Further divisions in opposite directions of each of these cell types generate an apical thallus and a basal rhizoid, respectively. In the gametophytes of *dis* mutants the basal germ tube that gives rise to the rhizoid is not produced. The consequent unipolar germination gives rise to individuals with an apical system but no basal structures. We suggest that the basal system is not produced because the *dis* mutants fail to deploy a putative basal determinant factor ('B') in the initial cell and, as a result, the first division produces an apical cell and a quiescent undifferentiated cell (Figure 7).

In the wild type sporophyte, the first division of the initial cell is symmetrical and the two germ tubes form the two ends of a basal filament, which is strongly attached to the substratum. In the absence of the DIS protein, the initial cell produces just one germ tube, which gives rise to the apical system. We interpret the failure to initiate a second germ tube as being a consequence of the failure to establish basal cell identity in the sporophyte of this mutant. We suggest that, in the absence of the basal determinant factor 'B', the initial cell divides to produce an apical cell and a quiescent undifferentiated cell in the same manner as observed in the gametophyte generation.

The *dis-2* mutation creates a premature stop codon within the region that encodes the TBCC domain and is therefore likely to be a null mutation. The *dis-1* mutation, on the other hand, is located in an intron (Figure 3). This mutation causes a reduction in transcript abundance but does not modify the open reading frame of the transcript. Analysis of the RNA-seq data did not detect any evidence that the mutation affects splicing of the transcript. Therefore, *dis-1* may not represent a null mutation. If *dis-1* is not a null allele, then under the model shown in Figure 7, the abortive structures produced instead of the second germ tube in *dis-1* mutant sporophytes can be interpreted as arising due to incomplete penetrance of the *dis-1* mutation, allowing a small amount of the putative basal determinant 'B' to accumulate, and the production of an abortive basal system.

18

515   The model proposes that the observed phenotypes are due to variations in
516   concentration, rather than the subcellular distribution, of the putative 'B' factor. One
517   possible scenario would be that the abnormal Golgi apparatus of the initial cell is unable
518   to produce sufficient amounts either of the putative 'B' factor itself or of a protein that
519   generates the 'B' factor enzymatically. Interestingly, comparison of the *dis-1*
520   transcriptome with those of wild type apical and basal tissues identified an enrichment in
521   genes coding for secreted proteins and highlighted a putative role for *DIS* in, among other
522   processes, cell wall modification processes, secretion, transport and vesicle trafficking.
523   Secretion and diffusion of cell fate determinants, particularly from the cell wall, have
524   been shown to play a crucial role in pattern formation in brown algae (Bouget et al.,
525   1998; Arun et al., 2013). Interestingly, mutant analysis indicates that cell wall synthesis,
526   cell wall integrity sensing, and vesicle trafficking are also important processes during the
527   development of *Marchantia polymorpha* rhizoids and *Arabidopsis* root hairs (Honkanen
528   et al., 2016).

529   In *Ectocarpus*, the apical and basal developmental programs appear to be independent,
530   in the sense that removal of the basal system in the *dis* mutants had no visible effect on
531   patterning of the apical system. In contrast, *Arabidopsis* mutations that result in the loss
532   of basal structures, such as *monopteros* and *bodenlos* for example, also tend to cause
533   more or less subtle modifications to the apical structures (Hardtke and Berleth, 1998;
534   Hamann et al., 1999). This difference may reflect the simpler developmental program of
535   *Ectocarpus* compared to *Arabidopsis* but may also be related to the fact that the primary
536   function of brown algal basal systems is to act as a holdfast, whereas the aerial tissues of
537   land plants are dependent on the root system not only for anchorage but also for water
538   and nutrient supply. In land plants, therefore, there may be more of a tendency for the
539   developmental programs of the apical and basal systems to be interdependent.

540   ***DIS* encodes a TBCC protein with a conserved role in intracellular organisation**

541   The *DIS* gene encodes a TBCCd1 protein. TBCCd1 is a member of the TBC group of
542   proteins, which also includes the retinitis pigmentosa protein 2 (RP2) and TBCC, a
543   component of the chaperone complex (TBCA to TBCE) that catalyses the formation of

544   α,ß-tubulin heterodimers (Tian and Cowan, 2013; Steinborn et al., 2002). All three
545   TBCC proteins have been strongly conserved across the eukaryotic tree (Figure 4D,
546   Supplemental Table 13) suggesting that each has a specific function in the cell. However,
547   whilst the role of TBCC has been described in detail, the exact cellular and molecular
548   function of TBCCd1 remains unclear.

549   The role of TBCC in the α,ß-tubulin heterodimerisation pathway is to trigger GTP
550   hydrolysis catalysing the release of newly formed αβ-tubulin heterodimers. Importantly,
551   this pathway is reversible so that TBCC plays a role in both microtubule assembly and
552   disassembly (Nithianantham et al., 2015). Both TBCC and RP2 have GAP activities,
553   mediated by their TBCC domains, and RP2 can complement a TBCC mutant (Schwahn
554   et al., 1998; Schwarz et al., 2012). In contrast, the TBCC domain of TBCCd1 lacks
555   several conserved residues including a critical arginine residue and TBCCd1 is thought
556   not to be a GAP protein (Bartolini et al., 2002; Scheffzek et al., 1998), although it has
557   been suggested that a nearby conserved arginine residue may substitute for the lost
558   arginine residue (Feldman and Marshall, 2009) (Supplemental Figure 9). Therefore,
559   although TBCCd1 probably interacts with the cytoskeleton in some way to mediate its
560   cellular functions, it is currently unclear whether this specifically involves a direct role in
561   microtubule polymerisation/depolymerisation.

562   TBCCd1 has been localised to the centrosome and the Golgi in organisms as diverse as
563   humans, *Chlamydomonas* and trypanosomes and loss-of-function experiments have
564   indicated a conserved and important role for TBCCd1 in various aspects of the
565   organisation of cellular architecture in these diverse eukaryote groups (André et al., 2013;
566   Feldman and Marshall, 2009; Goncalves et al., 2010). Loss or knockdown of TBCCd1
567   has severe consequences for cell morphology, for example leading to alterations in the
568   shape and motility of human cells (Goncalves et al., 2010), mitotic defects in
569   trypanosomes (André et al., 2013) and defects both in flagella number and functioning
570   and during cell division due to misorientation of the mitotic spindle in *Chlamydomonas*
571   (Feldman and Marshall, 2009). Although we did not detect any defects in flagella
572   structure or centriole positioning in *Ectocarpus dis* mutants, the initial cells of these
573   mutants did show defects in the positioning of the nucleus, and an atypical microtubule

20

network during germination. Moreover, *dis* initial cells were markedly larger than the wild type equivalents and their Golgi network was more abundant and fragmented (shorter cisternae). Increased cell size and disorganisation of the Golgi apparatus have been observed in TBCCd1-depleted human and trypanosome cells (Goncalves et al., 2010; André et al., 2013). The role of TBCCd1 in regulating organelle positioning, microtubule and Golgi architecture, highlighted by our study, can therefore be traced back to the crown divergence of the major eukaryotic groups, more than a billion years ago (Eme et al., 2014).

The Golgi defects in the *dis* mutants are particularly interesting with regard to the model described in Figure 7, which proposes that the Dis⁻ phenotype is due to failure to deploy a hypothetical basal-cell-fate-determining factor 'B' during the first cell division. In animals, the Golgi is critical for cellular differentiation and morphogenesis because it spatially constrains developmental pathways and it is required for the establishment of cell polarity and normal subcellular organization (Copeland et al., 2016; Vinogradova et al., 2009; Zhong, 2011). Moreover, in the embryo of the brown alga *Fucus*, targeted secretion from the Golgi to the cell wall has been implicated in axis fixation and establishment of the basal versus the apical system (Shaw and Quatrano, 1996).

In *Arabidopsis*, asymmetrical division of the zygote is preceded by reorganisation of the cytoskeleton and re-positioning of the nucleus from a central position to the apical region of the cell (Kimata et al., 2016; Ueda et al., 2011). Mutation of the zinc finger transcription factor gene *WRKY2* not only disrupts the asymmetrical division of the zygote cell but also leads to partial loss of basal identity in the basal cell lineage (Ueda et al., 2011). Interestingly, the *Ectocarpus dis* mutants not only fail to produce a basal system but also exhibit disrupted organisation of the microtubule cytoskeleton and defects in nucleus positioning in the initial cell. This suggests that, as in flowering plants, the establishment of the basal cell lineage in brown algae depends critically on events leading up to and including the first division of the initial cell.

It is not clear how loss of the TBCCd1 protein leads to disorganisation of the microtubule cytoskeleton in the *dis* mutants (whether this is a direct or an indirect effect

603 for example) but this phenotype does not appear to be simply due to defects in
604 microtubule polymerisation or depolymerisation because treatment with oryzalin or taxol
605 did not result in a phenotype that resembled that of the *dis* mutants. The observed
606 modifications to the microtubule architecture in *dis* mutants may be due to more subtle
607 changes in nucleating activity, rates of assembly and disassembly of bundles,
608 modifications of microtubule dynamic instability and/or tubulin or microtubule
609 posttranslational modifications (Mitchison and Kirschner, 1984; Song and Brady, 2015).

610 Based on the phenotypes associated with TBCCd1 loss in other eukaryotes and on the
611 phenotypes of the *dis* mutants, we propose that acquisition of basal cell identity in
612 *Ectocarpus* depends critically on features of the initial cell architecture, that are disrupted
613 in the absence of a functional DIS/TBCCd1 protein. Further work is required to
614 understand the exact cellular role of TBCCd1 in *Ectocarpus* but the identification of this
615 component will allow new insights into the cellular mechanisms involved in establishing
616 apical/basal identity.

617 **DIS and the evolution of sporophyte and gametophyte developmental programs**

618 The pattern of early development of the *Ectocarpus* sporophyte, which involves
619 deployment of an extensive basal system before the establishment of the apical/basal
620 axis, is unusual because most brown algal sporophytes exhibit early establishment of the
621 apical/basal axis leading directly to the production of a thallus cell and a rhizoid,
622 respectively (Fritsch, 1935). In the *Ectocarpus immediate upright* (*imm*) mutant the
623 extensive basal system of the sporophyte fails to form and this structure is replaced by a
624 rhizoid (Peters et al., 2008). Based on the phenotype of the *imm* mutant, we have
625 suggested that the pattern of early sporophyte development in extant *Ectocarpus* evolved
626 from a simpler, ancestral developmental program that more closely represented that of
627 the gametophyte, i.e. involving an asymmetrical initial cell division that gave rise directly
628 to apical and basal organs (Macaisne et al., 2017). The *dis* mutants provide further
629 support for this hypothesis because they exhibit complete loss both of the rhizoid during
630 the gametophyte generation and of the extensive network of prostrate filaments during
631 the sporophyte generation, suggesting that the two structures are indeed equivalent.

22

632 Moreover, in a *dis-1 imm* double mutant sporophyte the rhizoid that normally replaces the
633 prostrate filament system fails to develop, providing further evidence that the rhizoid that
634 forms in the *imm* mutant sporophyte is developmentally equivalent to the basal prostrate
635 filament system of the wild type sporophyte.

636   In land plants, which also have haploid-diploid life cycles, there has been considerable
637 interest in the evolutionary origins of the sporophyte and gametophyte developmental
638 programs; specifically whether each generation has independently evolved its own
639 developmental pathways or, alternatively, whether there has been recruitment of
640 developmental programs from one generation to the other during evolution (Dolan, 2009;
641 Pires and Dolan, 2012; Shaw et al., 2011). Current evidence indicates that the
642 developmental networks that implement land plant sporophyte programs were mainly
643 recruited from the gametophyte generation, which was initially the dominant generation
644 in the land plant lineage (Dolan, 2009; Niklas and Kutschera, 2010) but there is also
645 evidence that there have been sporophyte-specific innovations (Szovenyi et al., 2011;
646 Sano et al., 2005). Analyses of the *imm* (Macaisne et al., 2017) and *dis* (this study)
647 mutants suggest that the evolution of developmental systems in the brown algae also
648 involved both co-opting of programs from one generation to the other and generation-
649 specific developmental innovations. The phenotypes of the *dis* mutants suggest that,
650 despite their clear morphological differences, the basal systems of the sporophyte and
651 gametophyte generations share underlying mechanistic features because the TBCCd1
652 protein is necessary for the deployment of both types of basal structure. In this respect,
653 therefore, the sporophyte and gametophyte basal structures appear to be homologous. On
654 the other hand, it is only in the sporophyte that the rhizoid has been modified to produce
655 an extensive system of prostrate filaments (note that gametophytes carrying the *imm*
656 mutation are indistinguishable from wild type gametophytes; Peters et al., 2008). The
657 developmental program that depends on the IMM protein therefore appears to have been
658 a sporophyte-specific innovation, which was presumably built onto a more ancient
659 program shared with the gametophyte generation that requires the action of the *DIS* gene.

23

MATERIAL AND METHODS

UV mutagenesis and isolation of mutant strains

Strain cultivation, genetic crosses, raising of sporophytes from zygotes and isolation of meiotic families were carried out as described in (Coelho et al., 2012a, 2012d). Gametes of *Ectocarpus* are able to develop parthenogenetically to produce haploid partheno-sporophytes, which are identical morphologically to the sporophytes that develop from diploid zygotes (Peters et al., 2008; Coelho et al., 2011). This phenomenon was exploited to screen directly, in a haploid population, for mutants affected in early sporophyte development. UV mutagenesis of gametes was carried out as described previously (Godfroy et al., 2015) and mutant partheno-sporophytes lacking basal structures were identified by visual screening under a light microscope.

Genetic mapping of the *DIS* locus

To obtain an approximate map position for the *DIS* gene, the *dis-1* mutant (Ec722) was crossed with the outcrossing line Ec568 to generate a mapping population of 265 individuals. Each of the 265 individuals was derived from a different unilocular sporangium (each unilocular sporangium contains 50-100 meiospores, derived from a single meiosis followed by at least 5 mitotic divisions). The meio-spores germinated to produced gametophytes, which were isolated and allowed to germinate parthenogenically. The resulting partheno-sporophytes were then observed under a light microscope to determine whether they exhibited the Dis⁻ phenotype. The *dis-1* mutation was then approximately mapped using 21 Dis⁻ individuals from this segregating population and 74 microsatellites markers from the *Ectocarpus* microsatellite-based genetic map (Heesch et al., 2010). Using this approach, we localised the *dis-1* mutation to chromosome 05 at 9.5 cM from the M_114 marker.

A cloning-by-sequencing strategy (using the SHOREmap approach,(Schneeberger et al., 2009) was then used to precisely localise the *dis-1* mutation. Genomic DNA was extracted from 87 wild type and 96 *dis* individuals from the mapping population using

687   NucleoSpin® 96 Plant II (MACHEREY-NAGEL, Düren, Germany) and pooled into two

688   wild type and Dis⁻ pools. An Illumina HiSeq2500 platform (Fasteris, Genève, Suisse) was

689   the used to generate 44.9 Gb of sequence data, corresponding to 117 and 104 million 2x

690   100 bp paired-end reads for the wild type and Dis⁻ pools, respectively (SRA accession

691   numbers SRR3710253 and SRR3710254, respectively). The same DNA extraction

692   protocol and sequencing platform were employed to sequence the *dis-2* mutant strain

693   Ec799, producing 49 million 2x125 paired-end reads (SRA accession number

694   SRR3714421). Reads were cleaned to remove nucleotides with quality scores of less than

695   20 from both ends using Prinseq (Schmieder and Edwards, 2011). Reads were then only

696   retained if they were longer than 50 nucleotides, had a mean quality of at least 25 and no

697   non-determined nucleotides. About 3.6% and 4.3% of the raw wild type and *dis* reads

698   were removed, respectively. Bowtie2 (Langmead and Salzberg, 2012) was used to map

699   71.9% and 74.7% of the wild-type and *dis* cleaned reads, respectively, onto the Ec32

700   reference genome. The read mapping was then improved by read realignment and base

701   quality recalibration using the GATK software suite. Variant calling was carried out

702   using the "consensus" tool of the SHORE pipeline in order to analyse allele frequency.

703   Since we had only one reference genome sequence for *Ectocarpus*, corresponding to the

704   wild type strain that was mutagenised to generate the *dis* mutants, we were not able to

705   apply the strategy described in the SHOREmap publication to generate the list of markers

706   (association of SHOREmap extract and create). We therefore selected genetic markers by

707   comparing SNPs called in wild type and Dis⁻ pools and extracted SNPs that segregated as

708   expected, i.e., common SNPs for which the sum of the wild type and *dis-1* allele

709   frequencies was between 0.8 and 1.2. In order to prevent loss of markers close to the

710   mutation, we also included SNPs that were specific to one of each of the pools with a

711   frequency of more than 0.9 and less than 0.1. Using this marker list, and crossing

712   SHOREmap annotation results with manual selection of mutations from SHORE

713   consensus, SHORE qVar and samtools/VarScan (Koboldt et al., 2013; Schneeberger et

714   al., 2009) identified a unique SNP specific to the *dis-1* pool at position 50914 of scaffold

715   sctg_184 (position 3330523 on chromosome 5). This A to G transition mutation was

716   located in intron 14 of the *DIS* gene 15 base pairs after the end of exon 14.

A cleaved amplified polymorphic sequence (CAPS) marker (Supplemental Table 2), developed based on the single nucleotide polymorphism at position 3330523 of chromosome 05, was used to genotype the 265 individuals of the mapping population (which included 90 wild type and 175 *dis-1* individuals). This analysis confirmed that the presence of the A to G transition was 100% correlated with the Dis⁻ phenotype in this large family. In addition, PCR amplification and Sanger sequencing of the genomic region containing the mutation confirmed its presence in the *dis-1* mutant (Ec722) and its absence in the Ec32 and Ec568 strains (the original strain used for the mutagenesis and the outcross female line used to generate the segregating population, respectively).

Resequencing of the *DIS* gene in the *dis-2* mutant identified a point mutation (a C to T transition) in exon 13 that results in the introduction of a stop codon into the coding region of the gene (chr05, position 3332908).

Genetic interaction between *DIS* and *IMM*

An *imm* mutant female (Ec602) was crossed with a *dis-1* male (Ec722) and the resulting sporophyte (Ec649) gave rise to a 40-gametophyte progeny, all derived from independent meiotic events. The phenotypes of the progeny were scored under an inverted microscope, and genotypes were assessed using CAPS markers for *IMM* and *DIS* loci (Supplemental Table 2).

RNAi knockdown of *DIS* expression

Small interfering RNAs (siRNAs) directed against the *DIS* gene transcript were designed using version 3.2 of E-RNAi (Horn and Boutros, 2010). The specificity of the designed siRNAs was determined by comparing the sequence (Blastn) with complete genome and transcriptome sequences. Candidates that matched, even partially, genomic regions or transcripts in addition to *DIS* were rejected. Three siRNAs with predicted high specificity corresponding to different positions along the *DIS* transcript were selected (Supplemental Table 17). The control siRNA was directed against the *Ectocarpus* sp. gene Ec-13_001890 which is located within the sex-determining region of the male sex chromosome and therefore not an essential gene for sporophyte function. siRNAs were

A cleaved amplified polymorphic sequence (CAPS) marker (Supplemental Table 2), developed based on the single nucleotide polymorphism at position 3330523 of chromosome 05, was used to genotype the 265 individuals of the mapping population (which included 90 wild type and 175 *dis-1* individuals). This analysis confirmed that the presence of the A to G transition was 100% correlated with the Dis⁻ phenotype in this large family. In addition, PCR amplification and Sanger sequencing of the genomic region containing the mutation confirmed its presence in the *dis-1* mutant (Ec722) and its absence in the Ec32 and Ec568 strains (the original strain used for the mutagenesis and the outcross female line used to generate the segregating population, respectively).

Resequencing of the *DIS* gene in the *dis-2* mutant identified a point mutation (a C to T transition) in exon 13 that results in the introduction of a stop codon into the coding region of the gene (chr05, position 3332908).

Genetic interaction between *DIS* and *IMM*

An *imm* mutant female (Ec602) was crossed with a *dis-1* male (Ec722) and the resulting sporophyte (Ec649) gave rise to a 40-gametophyte progeny, all derived from independent meiotic events. The phenotypes of the progeny were scored under an inverted microscope, and genotypes were assessed using CAPS markers for *IMM* and *DIS* loci (Supplemental Table 2).

RNAi knockdown of *DIS* expression

Small interfering RNAs (siRNAs) directed against the *DIS* gene transcript were designed using version 3.2 of E-RNAi (Horn and Boutros, 2010). The specificity of the designed siRNAs was determined by comparing the sequence (Blastn) with complete genome and transcriptome sequences. Candidates that matched, even partially, genomic regions or transcripts in addition to *DIS* were rejected. Three siRNAs with predicted high specificity corresponding to different positions along the *DIS* transcript were selected (Supplemental Table 17). The control siRNA was directed against the *Ectocarpus* sp. gene Ec-13_001890 which is located within the sex-determining region of the male sex chromosome and therefore not an essential gene for sporophyte function. siRNAs were

745   introduced into *Ectocarpus* sp. strain Ec32 gametes using the transfection reagent

746   HiPerFect (Qiagen, Valencia, USA). One microlitre each of 0.5 μg/μl solutions of

747   siRNAs in 1X Universal siMAX® siRNA Buffer (MWG Eurofins, Ebersberg, Germany)

748   was mixed with 12 μl of HiPerFect transfection reagent in a final volume of 100 μl of

749   natural seawater, vortexed to mix and incubated for 10 min at room temperature before

750   being added dropwise to 100 μl of freshly released gametes in natural seawater in a Petri

751   dish. After rotating gently to mix, the Petri dish was incubated overnight at 13°C. The

752   following day, 10 ml of culture medium was added (Coelho et al., 2012c) and incubation

753   continued at 13°C. RNAi-induced phenotypes were observed under a light microscope

754   and the number of individuals that resembled the *dis* mutant were scored in at least 400

755   individuals for three experimental replicates. Control treatments were carried out in the

756   same manner using an siRNAs directed against the endogenous gene Ec-13-001890.

757   Unfortunately, it is currently not possible to determine whether the siRNA treatment

758   reduces *DIS* transcript abundance because, based on the observed phenotypes, gene

759   expression is affected in only a small percentage of the treated cells. However, the use of

760   an siRNAs directed against the endogenous gene Ec-13-001890 showed that the effect

761   was sequence-specific. It would therefore seem highly unlikely that the observed

762   phenotypes were due to processes that did not involve interference with the expression of

763   the *DIS* gene.

764   **Comparative transcriptome analyses**

765   RNA-seq analysis was carried out to compare the abundances of gene transcripts in the

766   *dis-1* mutant with those in basal and upright filaments of the wild type sporophyte

767   generation. Duplicate synchronous cultures (with more than 100 individuals each) were

768   prepared for each sample under standard conditions (Coelho et al., 2012c). Upright

769   filaments of adult (4-week old) wild type partheno-sporophytes were dissected from

770   prostrate, basal filaments using the sharp end of a Pasteur pipette under a binocular

771   microscope. Visual inspection under the microscope ensured the absence of

772   contaminating basal filaments. Wild type basal filaments were obtained by harvesting

773   immature individuals before the emergence of the upright filaments, two weeks after

774 initial cell release from plurilocular gametangia. The *dis-1* mutant was grown under the
775 same conditions as the wild type tissue and was similarly used at two weeks after release
776 of initial cells from plurilocular gametangia. Tissue samples were rapidly frozen in liquid
777 nitrogen and processed for RNA extraction. Total RNA was extracted from each sample
778 using the Qiagen Mini kit (http://www.qiagen.com) as previously described (Lipinska et
779 al., 2015). For each replicate, cDNA was produced by oligo-dT priming, fragmented and
780 prepared for 2x 100 bp paired end sequencing on an Illumina Hiseq 2000 platform by
781 Fasteris (CH-1228 Plan-les-Ouates, Switzerland). TopHat (v2.0.8) was used to map the
782 RNA-seq reads to the reference genome. Supplemental Table 18 provides details of the
783 sequencing, mapping statistics and accession numbers. Pairwise differential expression
784 analysis between *dis-1*, basal and upright filaments was performed with the DESeq2
785 package (Bioconductor) using an adjusted p-value cutoff of 0.1 and a minimal fold-
786 change of 2.

787 **Analysis of predicted gene functions**

788 InterProScan (Zdobnov and Apweiler, 2001) and Blast2GO (Conesa and Götz, 2008)
789 were used to recover functional annotations for *Ectocarpus* proteins. For Blast2GO, a
790 Fisher exact test with a p-value cutoff of 0.05 was used to detect enrichment of specific
791 GO-terms in the various groups of genes. KEGG pathway enrichment was analysed using
792 the KOBAS 2.0 platform (Xie et al., 2011). Signal peptides were predicted using Hectar
793 (Gschloessl et al., 2008) implemented through the Galaxy platform (http://webtools.sb-
794 roscoff.fr/). A gene-by-gene manual curation was used to associate each gene in the
795 differential transcriptomic datasets to a functional category. Enrichment in specific
796 functional categories in relation to the *Ectocarpus* sp. genome was carried out by
797 statistical analysis using Chi-squared test (P<0.05).

798 **Phylogenetic analysis of TBCC proteins**

799 A multiple alignment of the TBCC domains of diverse TBCC, RP2 and TBCCd1
800 proteins was generated with Muscle (http://www.ebi.ac.uk/Tools/msa/muscle/). Based on
801 this alignment, an unrooted maximum likelihood phylogenetic tree was built with the

802 LG+G model using MEGA7 (http://www.megasoftware.net/mega.php) and 1000

803 bootstrap replicates. Model testing was carried out in MEGA7. The coordinates of the

804 TBCC domains within the protein sequences were determined using the NCBI Conserved

805 domains tool (http://www.ncbi.nlm.nih.gov/Structure/cdd/wrpsb.cgi). Accession numbers

806 and domain coordinates are provided in Supplemental Table 14.

Microdissection and regeneration of *dis* mutants and wild type filaments

808 Microdissection was performed with the sharp end of a Pasteur pipette under an

809 inverted microscope. After dissection, the material was kept at 13°C under standard

810 culture conditions (Coelho et al., 2012e). Wild type and *dis* sporophyte apical filament

811 cells were isolated by micro-dissection 7 days after the emergence of the first upright

812 filaments (20 days after gamete release); gametophyte apical filament cells were isolated

813 by micro-dissection 15 days after meio-spore release.

Morphometric analysis of germinating partheno-sporophytes

815 Germinating initial cells of *dis-1*, *dis-2* and wild type partheno-sporophytes 36h after

816 release from gametangia were photographed under an upright microscope (BX41,

817 Olympus, Tokyo, Japan). Cell areas were measured for a total of 57 cells using ImageJ

818 (http://imagej.nih.gov/ij). Morphological measurements and analysis of images of adult

819 filaments were also performed under an inverted microscope (CKX41, Olympus, Tokyo,

820 Japan) using ImageJ (http://imagej.nih.gov/ij/, 1997-2016). Between 25 and 100 adult

821 filament cells were measured in each of eight different wild type or *dis-1* and *dis-2*

822 individuals. The statistical analysis was performed in R.

Electron microscopy analysis of cellular ultrastructure

824 Medium containing mature *Ectocarpus dis* partheno-sporophytes was pipetted onto a

825 plastic film (gel support films, ATTO CO., Tokyo, Japan). The film was cut into <1 cm

826 side triangles, and these were attached to Petri dishes by adhesive tape. Two days after

827 the release of mito-spores from plurilocular sporangia, the resulting germlings, which

828 were attached to the triangles, were rapidly immersed in liquid propane cooled to -180°C

29

829 by liquid nitrogen, and immediately transferred into liquid nitrogen. The samples were

830 submerged in substitution solution containing 2% osmium tetroxide with acetone at -

831 80˚C for two days, at -40°C for 2 h and at 4°C for 2 h. Finally, the temperature of the

832 samples was gradually allowed to rise to room temperature, and they were then washed

833 with acetone several times. The gel support films were infiltrated and embedded in

834 Spurr's low-viscosity resin (Polysciences Inc., Warrington, PA, USA) on aluminium foil

835 dishes. The films with the samples were turned inside out on the upper surface of the

836 resin. Serial sections were cut with a diamond knife on an ULTRACUT ultramicrotome

837 (Reichert-Jung, Depew, NY, USA) and mounted on formvar-coated slot grids. Sections

838 were stained with TI blue (Nisshin EM Co. Ltd, Tokyo, Japan) and lead citrate, and

839 observed using an electron microscope (JEM-1011, JEOL Ltd., Tokyo, Japan). The

840 images shown in Figure 5 are representative of 14 initial cells.

841 Golgi fragmentation was quantified using a method adapted from (Tang et al., 2011)).

842 Transmission electron microscope photographs were used to measure the lengths of

843 cisternae. Measurements were performed on 14 different individuals, and a total of 113

844 cisternae from *dis-1*, *dis-2* and wild type individuals were analysed. Data from *dis-1* and

845 *dis-2* were pooled. Cisternae were defined as long membranous structures with a length

846 greater than twice their width, the latter not exceeding 60 nm. Normal cisternae ranged

847 from 20 to 30 nm in width and were longer than 400 nm. Statistical significance was

848 assessed by a Wilcoxon test, implemented in R.

Quantitative reverse transcriptase PCR analysis

850 The abundance of gene transcripts during the *Ectocarpus* life cycle was assessed using

851 RT-qPCR. RT-qPCR was performed as previously described (Coelho et al., 2011;

852 Lipinska et al., 2013). Primer pairs were designed to amplify regions of the 3'UTR or the

853 most 3' exon of the gene to be analysed (Supplemental Table 19). *In silico* virtual PCR

854 amplifications were carried out using the e-PCR program (Rotmistrovsky et al., 2004)

855 and the male Ec32 genome sequence to check the specificity of oligonucleotide pairs.

856 The Plant RNeasy extraction kit (Qiagen, Courtaboeuf, France) was used to extract

857 total RNA from at least three biological replicates for each of the stages of the life cycle:

858 gametes, young sporophytes, immature gametophytes, mature gametophytes, partheno-
859 sporophytes and diploid heterozygous sporophytes. The RNA was treated with RNAse-
860 free DNAse-I according to the manufacturer's instructions (Qiagen) to remove any
861 contaminating DNA and stored at -80°C. The concentration and integrity of the RNA was
862 checked using a NanoDrop 2000 spectrophotometer (ThermoScientific,
863 www.thermofisher.com) and by agarose gel electrophoresis. A control PCR without
864 reverse transcriptase was performed to ensure absence of contaminating DNA. For each
865 sample, up to 1 µg of RNA was reverse-transcribed to cDNA using oligo-dT and the
866 Superscript II RT kit (Life Technologies, Gaithersburg, MD, USA) according to the
867 manufacturer's instructions and the cDNA was diluted with water to 1.2 ng equivalent
868 RNA.µL-1. cDNAs were amplified using the IQ Sybrgreen supermix (Biorad
869 Laboratories, Hercules, CA, USA) on a Chromo4 System thermocycler (BioRad
870 Laboratories). The amplification efficiency was tested using a genomic dilution series
871 and was always at least 80%. The specificity of amplification was checked with a
872 dissociation curve. The EF1α gene (Ec-21_002980) or the Arp2/3 gene (Ec-09_003710)
873 were chosen as a constitutively expressed controls based on (Le Bail et al., 2008) and
874 their constitutive expression was validated by the RNAseq datasets. The normalised data
875 were expressed as the mean±s.d. calculated from three independent biological
876 experiments.

877 **Inhibitor treatments**

878 Stock solutions of inhibitors were prepared in DMSO (oryzalin at 100 mM, taxol
879 (paclitaxel) at 5 mg/ml, and brefeldin A at 25 mg/ml) and working solutions were diluted
880 in half strength Provasoli-enriched seawater (PES)(Coelho et al., 2012d). Freshly
881 released *Ectocarpus* sp. gametes were settled in Petri dishes and treated for 24h with
882 0.01-1 µM oryzalin, 5-20 µM paclitaxel or 2.5-25 µg/ml brefeldin A (BFA). Controls
883 were treated with 0.002% DMSO. Cells were allowed to develop after removal of the
884 inhibitor and observations were performed four and seven days later, using an inverted
885 Olympus CKX41 microscope. For each experiment, between 19 and 310 individuals

886 were counted in triplicate dishes (529, 1071 and 2142 cells scored in total in each of the
887 oryzalin, paclitaxel and brefeldine A treatments, respectively; Supplemental Table 16).

888 **Immunostaining**

889 *Ectocarpus* samples were processed as described by (Coelho et al., 2012b) using an
890 adapted protocol from (Bisgrove and Kropf, 1998). Briefly, *Ectocarpus* cells were settled
891 on coverslips and at appropriate times after settlement were rapidly frozen in liquid
892 nitrogen and fixed in 2.5% glutaraldehyde and 3.2% paraformaldehyde for 1h, then
893 washed in PBS and treated with 5% Triton overnight. Samples were then rinsed in PBS
894 and 100 mM NaBH4 was added for 4h. Cell walls were degraded with cellulase (1% w/v)
895 and hemi-cellulase (4% w/v) for 1h, and the preparation was then rinsed with PBS and
896 blocked overnight in 2.5% non-fat dry milk in PBS. Samples were treated with anti-
897 tubulin antibody (1/200th, DM1A, Sigma-Aldrich) at 20°C overnight, and then treated
898 with the secondary antibody (AlexaFluor 488-conjugated goat anti-mouse IgG, Sigma-
899 Aldrich; 1:1000 in PBS) at 20°C overnight. The preparation was rinsed with PBS and
900 blocked overnight in 2.5% non-fat dry milk in PBS and then treated with anti-centrin
901 antibody (1/1000th anti-centrin 1 ab11257, Abcam) at 20°C overnight, followed by the
902 secondary antibody (1/1000th AlexaFluor 555-conjugated goat anti-rabbit IgG, Sigma
903 Aldrich) for 8h. Samples were stained with 4', 6-diamido-2-phenylindole (DAPI, 0.5
904 μg/ml in PBS) for 10 min at room temperature, and finally mounted in ProLong Gold
905 (Invitrogen).

906 **Confocal microscopy**

907 Confocal microscopy was conducted using an inverted SP8 laser scanning confocal
908 microscope (Leica Microsystem) equipped with a compact supply unit which integrates a
909 LIAchroic scan head, several laser lines (405 nm, 488 nm) and standard photomultiplier
910 tube detectors (PMT). We used the oil immersion lens HC PL APO 63x/1.40 OIL CS2.
911 The scanning speed was set at 400 Hz unidirectional. The pinhole was adjusted to one
912 Airy unit for all channels. The spatial sampling rate was optimized according to Niquist
913 criteria, generating a 0.058x0.058x0.299 μm voxel size (xyz). The Z-stack height fitted

914   the specimen thickness. A two-step sequential acquisition was designed to collect the

915   signal from three or four channels. The first step recorded the anti-tubulin fluorescence

916   signal (excitation 488 nm/emission 530 nm), and the transmitted light. The second step

917   acquired the DAPI fluorescence signal (excitation 405 nm/emission 415-480 nm) and the

918   anti-centrin signal (excitation 552 nm/emission 560-590 nm). Signal intensity was

919   averaged three times. The Fiji software was used to optimize the raw images, including

920   maximum intensity projection (MIP), and denoising (3*3 median filter). For any given

921   data, both wild-type and mutant images were analysed simultaneously with similar

922   settings. The Fiji software was also used to estimate the number of microtubule bundles

923   in each cell, before the first cell division. Tracking of bundles was performed on

924   maximum intensity projections of z-planes covering the whole thickness of the cells. We

925   drew three lines transversely, perpendicular to the growth axis of the cell: one in the

926   centre of the cell, and other two half way between the centre and the cell extremities (see

927   diagram in Figure 6D). Peaks corresponding to the microtubule bundles were then

928   identified in plots of intensity profiles at each of the three positions in the cell and

929   counted. The three values were averaged for each cell to derive an estimation of the

930   number of microtubule bundles in each cell. Note that in the *dis* mutants, due to the

931   disorganised nature of the microtubule network, average bundle numbers may be

932   somewhat underestimated. This is because this method is well adapted for tracking

933   microtubule bundles oriented with their long axis parallel to the image plane, but we may

934   have missed bundles that were perpendicular to the plane of the transection.

935   **Measurement of the positions of nuclei and microtubule nucleation sites**

936   Nuclei were stained *in vivo* with Hoechst 33342 (Thermofisher), imaged with an

937   Olympus BX microscope with a x40 objective, and distances were measured using Fiji

938   software. In germinating initial cells, the position of the nucleus was calculated by

939   measuring the distance from the nucleus to the germinating pole (i.e. the end

940   corresponding to the emerging germ tube) and the distance from the nucleus to the

941   opposite pole of the cell and dividing the latter by the former. Nuclei were scored as

942   being anterior (located near the emerging germ tube), central or posterior (located nearer

943   the pole opposite the germination pole). At the 2-cell stage, the positions of nuclei were

944   similarly measured in a directional manner by measuring the distance from the nucleus to

945   the cell boundary at the germinating end of the filament and the distance from the nucleus

946   to the opposite pole of the cell and dividing the latter by the former. For cells in

947   multicellular filaments at a later stage of development, it was not possible to assign a

948   direction of growth. Filaments were therefore orientated arbitrarily and the position of

949   each nucleus was calculated by dividing the distance from one end of the cell (x) by the

950   distance from the other end of the cell (y) as illustrated in Figure 6H.

951   Microtubule nucleation site positions were measured by dividing each cell into four

952   diagonal quadrants and scoring the position of the nucleating sites with respect to these

953   quadrants: proximal (located on the same pole as the emerging germ tube), lateral or

954   distal (located nearer the pole opposite the germination pole) as illustrated in Figure 6F.

955   **Accession numbers**

956   Accession numbers are provided in Supplemental Table 18.

957 # Supplemental Data
