1 Abstract

Cell wall (CW) degradation causes texture loss of plant-based products after 2 processing. However, these losses differ in intensity, which could be due to cell wall 3 structure or plant tissue internal pH conditions. To distinguish these two factors, CWs 4 isolated from apple, beet and kiwifruit were subjected to boiling at pH 2.0, 3.5 and 6.0. 5 Pectin depolymerization was the least pronounced at pH 3.5, while galacturonic acid 6 7 contents of all CWs decreased at pH 6.0 due to the β-elimination. Pectins were solubilized, and their size decreased with increased pH during CW treatment. At pH 8 6.0, degrees of methylation decreased mostly in apple and beet CWs while galactose 9 10 decreased more in kiwifruit CW. At pH 2.0, arabinan was lost in apple and beet CW due to acid hydrolysis. Apple CW was the most susceptible to degradation either at 11 12 pH 2.0 or 6.0, while beet CW was more degraded at pH 2.0. In contrast, kiwifruit CW was the least susceptible to degradation whichever the pH. Acid hydrolysis and 13 β -elimination appeared to be common mechanisms that cause loss of neutral sugars, 14 often from pectin side chains, and galacturonic acid, respectively, but their effects 15 16 were of different intensities. This work has a guiding significance for improving 17 texture in the thermally canning process.

26 **1 Introduction**

27 Cell walls and their constituent polysaccharides play an important role in plant-based foods, where they control the texture and its evolution during maturation 28 and processing (Ranganathan, Subramanian, & Shanmugam, 2016). Plant cell walls 29 are a complex, porous, polysaccharidic material composed of cellulose, 30 31 hemicelluloses and pectins. The relative amounts of these constituents are dependent 32 upon the species and maturity of plant tissue. Plant-based foods are commonly 33 processed, e.g. cooking and canning, before being consumed to improve palatability and for a microbiological stability (M. Li, Ho, Hayes, & Ferruzzi, 2019). The first 34 steps of cell wall modification during processing, which involve the endogenous 35 pectinases and their synergies, have been extensively studied as a function of 36 37 temperature and pressure (Sila et al., 2009). However, it is difficult to control the action of endogenous enzymes during the first phase of heating. Many articles also 38 describe texture loss of plant tissues after enzyme inactivation or thermal processing, 39 40 but each concerns a single plant material at its natural pH (from 3.0 - 6.5), such as apple (Le Bourvellec, Watrelot, Ginies, Imberty, & Renard, 2012), apricot (Ella 41 Missang, Maingonnat, Renard, & Audergon, 2012), pear (Renard, 2005a), radish 42 (Ando, Hagiwara, & Nabetani, 2017; X. Li, Liu, Tu, Li, & Yan, 2019), potato (Zhao, 43 Shehzad, Yan, Li, & Wang, 2017) or asparagus (Peng, Song, Zhang, Pan, & Tu, 2019). 44 Different plant sources with their natural pH values may have specific responses to 45 46 processing, and common responses may occur at distinct extents. However, it is difficult from the existing literature to ascertain whether these different responses are 47

due to the structure of the cell walls or to the conditions during fruit and vegetable (F&V) processing. Notably, the natural internal pH is known to be a major driver for the degradation of polysaccharides, and primarily of pectins. It is therefore important to obtain a clear picture differentiating between the effects of the cell wall structure and the pH conditions during F&V processing.

53 Non-enzymatic cell wall modifications during processing involve an increased solubilization accompanied by a depolymerization of pectins (Fraeye et al., 2007). 54 Cellulose and hemicelluloses show minimal structural changes compared to pectins, 55 which therefore appear to be a key to texture loss (Houben, Jolie, Fraeye, Van Loey, & 56 Hendrickx, 2011). Many studies were done using purified pectins heated in model 57 solutions, at different pHs (Chen et al., 2015; Diaz, Anthon, & Barrett, 2007; Fraeye 58 59 et al., 2007), but we did not find any comparable model studies on complex cell wall 60 matrices. Moreover, work on the impact of thermal processing on the cell wall is mainly focused on the entire plant tissue, but confounding parameters such as the cell 61 62 wall structure and degradation in pH conditions were not controlled (at natural pH) (Renard, 2005a; Ella Missang et al., 2012; Zhao et al., 2017; X. Li et al., 2019). The 63 chemical mechanisms vary with pH conditions. β -elimination, which is specific for 64 65 methoxylated pectins, cleaves the methoxylated homogalacturonan chains creating an unsaturated bond (between C4 and C5 of a methoxylated uronic acid) with absorption 66 at 235 nm (Albersheim, Neukom, & Deuel, 1960). Pectins with a higher degree of 67 methylation (DM) are more sensitive to β -elimination (Fraeye et al., 2007). 68 β-elimination is in competition with saponification of methoxylated galacturonic acids, 69

70	which is favoured by high pH. As temperature increases, the rate of β -elimination
71	increases faster than that of demethylation, so that heating at a neutral to slightly
72	acidic pH (> 4.5) may lead to an extensive pectin depolymerization. During thermal
73	treatment in acidic conditions (pH \leq 3.0), acid hydrolysis occurs, leading to a loss of
74	pectin side-chains, starting with arabinans, and a cleavage in the rhamnogalacturonan
75	I regions of pectins, in the order of sensitivity of the glycosidic bonds in a following
76	order: Ara - Ara > Gal - Gal > Rha - GalA > GalA - Rha > GalA - GalA (Renard,
77	Crépeau, & Thibault, 1995). In this condition, the rate of hydrolysis of pectins with
78	low DM is faster (Fraeye et al., 2007). The β -elimination reaction and acid hydrolysis
79	may occur simultaneously when the heating is performed at a weakly acidic pH, with
80	the maximal stability of pectins being observed at circa pH 3.5. As the pH increases,
81	the reaction rates of β -elimination increase whereas they decrease for the acid
82	hydrolysis (Fraeye et al., 2007; Smidsrød et al., 1966). Therefore, in order to avoid
83	confounding factors like action of endogenous enzymes at the beginning of heating,
84	tissue structure and natural pH without control, three pH values (2.0, 3.5 and 6.0)
85	were chosen to explore how the balance between β -elimination and hydrolysis affects
86	pectins within the multi-scale structure of purified cell walls.

Two fruits (apple and kiwifruit) and one vegetable (beet) were chosen because the structure and composition of their cell walls are different (Latorre, de Escalada Plá, Rojas, & Gerschenson, 2013; Le Bourvellec et al., 2011; Redgwell, Melton, & Brasch, 1988), as well as their responses to processing and their internal pH values. Since there is little information about the modification of the kiwifruit cell wall, we

92 separately compared the phenomenon at two maturity stages. To schematize, apple cell walls are rich in highly methylated pectins, beet cell walls are rich in arabinans 93 94 and pectins of intermediate DM, while kiwifruit cell walls have few pectins with very few side-chains. Apple rapidly loses its texture upon heating (less than 30 min, (Kebe, 95 96 Renard, El Maâtaoui, Amani, & Maingonnat, 2015)), while beet fails to soften 97 completely after several hours, which may be due to the ferulic acid cross-linking of pectins (Waldron, Ng, Parker, & Parr, 1997). The texture loss of kiwifruit is also 98 limited but with different responses to processing according to ripe and overripe 99 100 stages, and show extensive swelling after ripening (Redgwell et al., 1997).

Therefore, our aim was to identify whether common chemical mechanisms 101 102 (β-elimination and acid hydrolysis) or specific cell wall composition and structure had 103 a higher impact on the cell wall susceptibility to degradation. The originality of this 104 study is that purified cell walls from apple, beet and kiwifruit, were first isolated then subjected to boiling (20 min) at pH 2.0, 3.5 and 6.0, allowing an independent 105 106 variation of cell wall structure and pH. The surface topography of the cell walls was visualized using scanning electron microscopy (SEM). Native and modified cell walls 107 108 as well as extracted solubilized polysaccharide compositions were analyzed. The 109 extent of degradation of solubilized polysaccharides was studied using 110 HPSEC-MALLS. This work provides some implications for the fruit and vegetable processing, such as the fine-tuning of pH conditions that may improve the quality of 111 thermally processed plant-based products. 112

113 2 Materials and methods

114 **2.1 Standards and Chemicals**

Ethanol and acetone were from Fisher Scientific (Strasbourg, France). 115 Acetonitrile of HPLC grade was obtained from VWR International (Radnor, USA). 116 117 Hexane, methanol, hydrochloric acid and acetic acid were from Merck (Darmstadt, Germany). Sugar standards (arabinose, fucose, galactose, xylose, mannose and 118 119 rhamnose) and polygalacturonic acid were from Fluka (Buchs, Switzerland). Formic sodium carbonate, sodium hydroxide, 120 acid. benzyl mercaptan, NaBH₄. N-methylimidazole, acetic anhydride, lignin alkali, toluene-a-thiol, (+)-catechin, 121 (-)-epicatechin, inositol and galacturonic acid were provided from Sigma-Aldrich 122 (Saint Quentin Fallavier, France). Methanol-d₃ was from Acros Organics (Geel, 123 Belgium). 124

125 2.2 Plant Material

Apple fruits (*Malus* \times *domestica* Borkh.) from the 'Golden Delicious' cultivar, 126 127 beets (Beta vulgaris L.) from the round red beetroot type, and kiwifruits (Actinidia deliciosa) from the 'Hayward Green' cultivar were purchased at commercial maturity 128 in September 2017 at the supermarket (Auchan, Avignon, France). For kiwifruits, two 129 130 maturity stages were studied: "Ripe" corresponding to kiwifruits at the date of purchase and "Overripe" (described as "soft under the fingers") obtained after three 131 weeks at 10 °C followed by one week at room temperature (26 °C). To quantify this 132 133 evolution, the kiwifruit flesh firmness was measured using a multi-purpose TAplus Texture Analyser (Ametek, Lloyd Instruments Ltd., Fareham, UK). Kiwifruits were 134

peeled in a 10 \times 10 mm area on the upside and downside, placed on a stationary 135steel plate and penetrated to depth of 50 mm with a 12.57 mm^2 probe at a speed of 5 136 137 mm/s. A batch of five fruits was constituted for each maturity stage. Two determinations were conducted on the two opposite sides of each fruit. Clear texture 138 139 differences were obtained with respectively 1.4 ± 0.41 N (eating-ripe, soft) and $0.6 \pm$ 140 0.31 N (overripe, very soft). All plant materials were peeled, apples were cored, kiwifruits were cored and deseeded, and cortex tissues were used for the preparation 141 142 of cell wall materials.

143 **2.3 Preparation of cell wall**

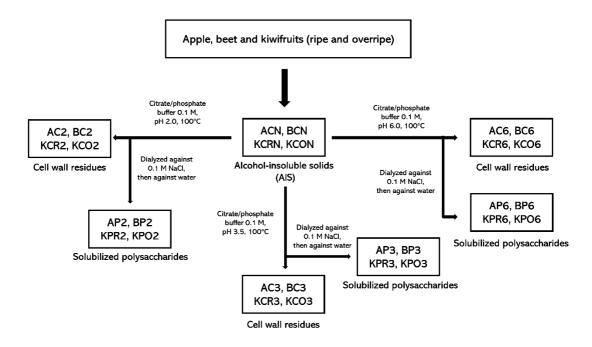

Alcohol-insoluble solids (AIS) were prepared from apple (pH 3.8), beet (pH 5.0) and kiwifruit (pH 3.4 for ripe and 3.3 for overripe) according to the method of Renard (2005). More than 10 batches of 0.5 to 1.0 kg were processed for each plant material, then mixed to obtain an uniform sample. The samples were named as apple native cell wall (ACN), beet native cell wall (BCN), ripe kiwifruit native cell wall (KCRN) and overripe kiwifruit native cell wall (KCON), respectively.

150 **2.4 Modification of cell walls by boiling at different pH values**

The cell walls (25 g/L) were separately incubated in a citrate/phosphate buffer (pH 2.0, 3.5, and 6.0; 0.1 M) in sealed glass bottles in a boiling water bath for 20 min. After treatments, the cell walls and the buffer solution were separated by hot filtration under vacuum in a G0 sintered glass filter. The cell walls were dried by solvent exchange using 96% ethanol (three times) and acetone (three times), then overnight in
an oven at 40 °C.

The cell wall samples after boiling at pH 2.0, 3.5, and 6.0 are designated (AC, BC,
KCR or KCO) - 2, (AC, BC, KCR or KCO) -3, and (AC, BC, KCR or KCO) - 6,
respectively.

- The buffer solutions containing solubilized polysaccharides (SP) were dialyzed (a
 dialysis tube of theoretical porosity of 12 kDa, Sigma Chemical Co., St. Louis, MO,
 USA) against 0.1 M NaCl during 48 h, and then against water before freeze-dring. SP
- at pH 2.0, 3.5, and 6.0 are designated (AP, BP, KPR or KPO) 2, (AP, BP, KPR or
- 164 KPO) -3, and (AP, BP, KPR or KPO) 6, respectively (Fig. 1).

165

Figure 1. Scheme of AISs preparation, cell walls modification and solubilized polysaccharides
extraction at three pHs from apple, beet and kiwifruit. Abbreviations: A, Apple; B, Beet; K, Kiwifruit;
C, cell walls; P, solubilized polysaccharides; 2, pH 2.0; 3, pH 3.5; 6, pH 6.0; R, Ripe; O, Overripe.

169 **2.5 Surface morphology analysis by scanning electron microscopy (SEM)**

170 Samples were mounted on SEM specimen stubs with a carbon double-sided, carbon-conductive, adhesive tape prior to coating. Samples were then coated with 20 171172 nm gold layers by ion sputtering using Balzers SCD 004 sputter coater (Balzers, Bal Tec.AG, Furstentum, Lichtenstein) and subsequently photographed using a 173 The Netherlands) scanning 174PhilipsXL30 (FEI/Philips, Eindhoven, electron 175microscope operated at an accelerating voltage of 10 kV.

176 **2.6 ATR-FTIR spectra**

The spectral data of cell walls and solubilized polysaccharides were both acquired 177 with a Tensor 27 FTIR spectrometer (Bruker Optics[®], Wissembourg, France). Native 178 cell walls and modified cell walls were stored in P₂O₅ atmosphere before analysis to 179 remove residual water. ATR-FTIR spectra were acquired at room temperature on 180 sample powder using a single-reflectance horizontal ATR cell (Golden Gate equipped 181 with a diamond crystal, Bruker Optics) as described by Bureau et al. (2012), by 182 scanning from 4000 to 600 cm⁻¹ and correcting against the background spectrum of air. 183 Each sample was analyzed three times, and each spectrum was an average of 16 scans. 184 Spectral pre-processing and data treatment using multivariate analyses were 185 performed with Matlab 7.5 (Mathworks Inc. Natick, MA) software using SAISIR 186 187 package (Cordella & Bertrand, 2014). The spectral data were transformed with baseline correction and standard normal variate (SNV) to correct multiplicative 188 interferences and variations in the baseline shift before any multivariate analysis. A 189 Principal Component Analysis (PCA) was applied using FT-IR spectra in the range 190 between 2000 and 600 cm⁻¹ to evaluate the distribution of the different samples 191

192 (species and pH treatments).

193 2.7 High-Performance Size-Exclusion Chromatography Coupled with 194 Multi-Angle Laser Light Scattering (HPSEC-MALLS)

The molar mass distribution of SP was determined using a HPSEC system 195 involving a Ultra Fast Liquid Chromatography Prominence system (Shimadzu, Kyoto, 196 Japan) including a LC-2OAD pump, a DGU-20A5 degasser, a SIL-20ACHT 197 198 autosampler, a CTO-20 AC column oven, a SPD-M20A diode array detector and a 199 RID-10A refractive index detector. In addition, a multi-angle laser light scattering (MALLS) detector DAWN HELEOS 8+ (fitted with a K5 flow cell and a GaAs laser 200 at $\lambda = 660$ nm) from Wyatt Technology Corporation (Santa Barbara, CA) was coupled 201 with the HPSEC system. Separations were achieved at 40 °C using three HPSEC 202 columns in series (PolySep-GFC-P3000, P5000 and P6000 300 ×7.8 mm) and a guard 203 204 column from Phenomenex (Torrence, CA, USA). 100 µL of SP (2.5 mg/mL) solutions were injected and eluted at 0.6 mL/min using a 0.1 M citrate/phosphate buffer at pH 205 3.8, previously filtered through a 0.1 µm, OmniporeTM membrane (Millipore, Milford, 206 207 USA) and degassed. Before injection, SP were solubilized under magnetic stirring in the filtered eluant at 4°C overnight. The solutions were centrifuged 10 min at 8000 g 208 209 and the supernatant was filtered through a 0.45 µm hydrophilic PTFE syringe filter 210 (Macherey-Nagel, Düren, Germany) before injection. M_i, the molar mass at each slice of the chromatogram, was determined using the concentration and the light scattering 211 signal from 5 angles (from 20.4 $^\circ$ $\,$ to 90 $^\circ$) and data extrapolation to zero angle using 212 the Zimm formalism with a one order polynomial fit (Rolland-Sabaté, Colonna, 213

Potocki-Véronèse, Monsan, & Planchot, 2004). Then, the weight-average (\overline{M}_w) was calculated using the summations taken over the whole peaks using ASTRA® software from Wyatt Technology Corporation (version 7.1.4 for PC) as previously described (Rolland-Sabaté et al., 2004). A value of 0.146 mL/g was used as the refractive index increment (dn/dc) for glucans and the normalization of photodiodes was achieved using a low molar mass pullulan standard (P20) from Showa Denko K.K. (Tokyo, Japan).

221 **2.8 Chemical composition analysis**

222 **2.8.1 Hydrolysis**

For cell walls, approximately 10 mg of AIS were prehydrolyzed with 72% sulfuric acid (250 μ L) for 1 h at 26 °C (Saeman, Moore, Mitchell, & Millett, 1954), before dilution to 1 M sulfuric acid by the addition of water and an internal standard (inositol); simple hydrolysis was also carried out to estimate cellulose content by difference. For SP, the sample was directly dissolved in 1 M sulfuric acid with internal standard without prehydrolysis. All samples were hydolysed at 100 ° C for 3 hours.

229 **2.8.2 Neutral sugar composition**

Neutral sugars were analyzed as alditol acetates (Canteri, Renard, Le Bourvellec, & Bureau, 2019; Englyst, Wiggins, & Cummings, 1982). The samples were injected in a GC-FID HP 5890 Series II (Agilent, Inc., Palo Alto, USA) equipped with a capillary column (30 m \times 0.25 mm i.d. coated with DB225 MS, 0.25 μ m film thickness) using: split mode (1:25 ratio); injector temperature 250 °C; hydrogen as carrier gas at 45 cm/s (215 °C); column flow 1.3 mL/min and oven temperature
236 215 °C (isothermal).

237 **2.8.3 Galacturonic acid content**

Uronic acids were measured by the meta-hydroxyl-diphenyl assay as described by (Blumenkrantz & Asboe-Hansen, 1973; Canteri et al., 2019) after Saeman hydrolysis (§ 2.8.1). The absorbance was read at 520 nm using a spectrophotometer (V-530 Jasco, Tokyo, Japan), and concentrations were calculated against a calibration curve with galacturonic acid as external standard.

243 **2.8.4 Methanol and degree of methylation**

The methanol content was measured by stable isotope dilution assay using headspace-GC-MS (QP2010 Shimadzu, Kyoto, Japan) as described by Renard & Ginies (2009) after saponification. The degree of methylation (DM) was calculated as molar ratio of methanol to galacturonic acid.

248 2.8.5 Lignin content

Lignin was measured spectrophotometrically (V-530Jasco, Tokyo, Japan) as described by Metaxas, Syros, Yupsanis, & Economou (2004) with alkali lignin as external standard. Cell wall samples (15 mg) were digested in 1 mL 25 % acetyl bromide in acetic acid containing 2.7% (v/v) perchloric acid and incubated for 30 minutes at 70 °C. The samples were cooled and 10 μ L were transferred into a test tube, then 570 μ l of 17 % 2N NaOH and 83 % acetic acid were added, followed by 20 μ L of 7.5 M hydroxylamine hydrochloride to stop the reaction. The volume was corrected

256	to 2 mL with acetic acid and the absorbance was read at 280 nm using a
257	spectrophotometer V-530 (Jasco, Tokyo, Japan). The amount of lignin was calculated
258	from a linear calibration curve with commercial alkali lignin as standard.

259

2.8.6 Procyanidin content

Procyanidins were measured by HPLC-DAD after thioacidolysis as described by Guyot, Marnet, & Drilleau (2001). Their characterization and quantification were performed using an Ultra Fast Liquid Chromatography Prominence system (Shimadzu, Kyoto, Japan) controlled by the LabSolutions software (Version 5.57, Shimadzu, Kyoto, Japan). Separation conditions, identification and quantification were performed as described (Guyot et al., 2001; Le Bourvellec et al., 2011).

266 **2.8.7 Acetic acid content**

Acetic acid was released by saponification and quantified according to the acetic 267 acid assay kit (K-ACET, ACS Manual Format, Megazyme International, Ireland). 268 269 Samples (10 mg) were incubated in 5 ml NaOH 0.2 M for 3 h. 2 ml deionized water, 0.1 ml sample, 0.5 ml buffer (30mL, pH 8.4) plus L-malic acid and sodium azide 270 271 (0.02 % w/v), and 0.2 ml NAD+/ATP/PVP/CoA solution were added into cuvettes and mixed. The absorption was read at 340 nm (A0) after approx. 3 min using a 272 spectrophotometer V-530 (Jasco, Tokyo, Japan). Then the reaction was started by 273 addition of 20 µl L-malate dehydrogenase plus citrate synthase suspension. The 274 275absorption was read at 340 nm (A1) after approx. 4 min and the reaction was started again by addition of 20 µl acetyl-coenzyme a synthetase suspension. The reaction 276

misture was mixed and the absorbance of the solutions (A2) at the end of the reaction (approx. 12 min) was read at 340 nm. The acetic acid content was calculated based on an acetic acid standard curve using $Mega-Calc^{TM}$ software tool (Megazyme International, Ireland).

281 **2.8.8 Ferulic acid content**

282 Ferulic acid was released by saponification according to the method of Micard, Renard, & Thibault (1994). Samples (25 mg) were incubated in 25 mL of 2 M NaOH 283 at room temperature for 1 h under a stream of argon followed by two hours at 35 °C. 284 The extracts were filtered on G1 sintered glass filters, adjusted to pH 2.0 by fuming 285 hydrochloric acid and extracted by ethyl acetate (3 times). The upper organic phases 286 287 were recovered, dried over anhydrous Na₂SO₄, filtered and evaporated. The dry extracts were taken up in 1 mL of methanol and 20 µL were injected into the 288 289 HPLC-DAD system (§2.8.5) with detection at 320 nm.

290 2.9 Statistical Analysis

Results are presented as mean values of analytical triplicates and the reproducibility of the results is expressed as pooled standard deviations (Pooled SD). Pooled SD were calculated for each series of replicates using the sum of individual variances weighted by the individual degrees of freedom (Box, Hunter, & Hunter, 1978). Analysis of variance (ANOVA) was performed using Excelstat package of Microsoft Excel. Spectral pre-processing and Principal Component Analysis (PCA) were performed using MATLAB 7.5 (Mathworks Inc. Natick, MA) software using the 298 SAISIR package (Cordella & Bertrand, 2014).

299 **3 Results and discussion**

300 **3.1 Surface morphology of cell walls**

301 Apple, beet and kiwifruit cell wall preparations had thin cell walls and showed a network of empty cells of irregular shape and size (Fig. 2). The kiwifruit cell wall 302 preparations exhibited the smallest cavities, non-porous and compact, with a wrinkled 303 304 appearance comparable to tree cuticles or the surface of mountain heavily eroded by wind and sand. These preparations contained sieve tubes in xylem and phloem tissues 305 306 and thin rods, probably raphide crystals of calcium oxalate, as described previously in 307 kiwifruit (Redgwell et al., 1988). The surface of the apple cell walls was the flattest and had large empty spaces, followed by beet cell walls. The tissular structure of beets 308 309 was similar to a honeycomb, with thin interconnected walls, matching earlier studies (Dongowski, 2001). 310

311 All treatments, whichever the pH and cell wall, seemed to have similar effects on the surface morphology of cell walls, i.e., all cell walls became more wrinkled and 312 313 crumpled. The appearance of cell walls treated at pH 3.5 was the most similar to those 314 of the initial cell walls. In apple and beet cell walls treated at pH 6.0, the cell walls became less smooth and some regular patterns were faintly visible, so that a 315 316 substructure seemed to emerge, probably linked to the organization of the cellulose microfibrils (McCann, Wells, & Roberts, 1990), but the treatment was not sufficient to 317 clearly reveal it. Rougher surfaces were obtained for kiwifruit cell walls, notably after 318

overripening. Another remarkable point was the persistence of calcium oxalate crystals in the kiwifruit cell wall preparations after treatment at pH 3.5. Heating and drying can modify the physical properties of the cell wall material by inducing collapse of β -glucans and pectins (Le Bourvellec & Renard, 2005). However, in the present case, all cell walls were subjected to hydrothermal treatment and gentle drying. Therefore, less modifications were observed, compared with apple cell walls dried in harsh conditions (Le Bourvellec & Renard, 2005).

344 **3.2** Characterization of native and modified cell walls after boiling at three 345 different pHs

346 **3.2.1 Global characterization by FTIR spectra**

A principal component analysis (PCA) was carried out using the spectral data 347 (Fig. 3) to highlight the distribution of all AIS samples. The first two axes (PC1 and 348 PC2) explained more than 82% of the total variance and allowed the discrimination of 349 350 the three species, apple, beet and kiwifruit (Fig. 3A). Since the composition of apple and beet cell walls are very different (Latorre et al., 2013; Le Bourvellec et al., 2011), 351 one would have expected the samples according to their spectra to be separated on the 352 353 PC1 x PC2 plane. However, this was not the case, indicating that the complex internal cross-linking type in cell walls may also influence the spectral data and not only 354 chemical composition per se. Concerning the treatments (at pH 2.0, 3.5 and 6.0), the 355 356 samples were also separated in four groups (one for each treatment plus the non treated cell walls) for each species (Fig. 3A). PC1 discriminated cell walls at pH 2.0 357 22

358 on the left and pH 6.0 on the right in each species group, highlighting a common impact. Samples treated at pH 3.5 were close to the native cell walls, at least along 359 PC1. The study of eigenvectors (Fig 3B) and especially of PC1 showed two negative 360 peaks at 1740 and 1028 cm⁻¹ which could be due to galacturonic acid and its ester 361 carbonyl group absorptions whereas the positive peak at 1633 cm⁻¹ could be due to its 362 363 free carbonyl group (Gnanasambandam, Proctor, 2000; Kohn, 1975; Szymanska-Chargot & Zdunek, 2013). The positive peak at 1526 cm⁻¹, characteristic 364 of kiwifruit cell walls, might be due to lignin (Huck, 2015). PC1 thus differentiated 365 366 apple and beet cell walls (pectin-rich) from kiwifruit cell walls (pectin-poor), and within each species group common mechanisms, probably also linked to the pectic 367 backbone. 368

PC2 only expressed 10% of the variability and presented bands linked to galacturonic acid and neutral sugars, but sample discrimination was more variable per species. Two kinds of samples stood out along PC2, namely apple cell walls treated at pH 2.0 (lower) and kiwifruit cell walls treated at pH 3.5 (higher than the initial cell walls). For apple and beet cell walls, all the treatments resulted in a shift in the same direction along PC2, but not for the kiwifruit cell walls. This PC could thus be more related to specific effects.

376 **3.2.2 Native cell wall yields**

377 The cell walls of the apples, beets and kiwifruits were pure white, reddish gray 378 and light grayish white, respectively. The beet cell wall yields (Table 1) were twice those of apple and kiwifruit. The cell wall yields were comparable to, though generally slightly lower than, those reported earlier: for apple 17.2 to 27 mg/g (FW, fresh weight) (Le Bourvellec et al. (2011), 12 cultivars); for beet 30.4 mg/g (Dongowski (2001) and 36 mg/g (FW) (Latorre et al. (2013), after 10 min boiling); for kiwifruit 32.1 mg/g FW with whole, unpeeled kiwifruits (Sauvageau, Hinkley, Carnachan, & Sims, 2010), and 16 mg/g FW with outer parenchyma (Fischer, Wegryzn, Hallett, & Redgwell, 1996).

386 **3.2.3 Compositions of native and modified cell walls**

Native cell wall compositions were in agreement with literature data (Le Bourvellec et al., 2011; Redgwell et al., 1988; Renard & Thibault, 1993). Concerning polysaccharides, the cell walls of all three species were rich in glucose and galacturonic acid (Table 1). Glucose was mainly derived from cellulose. Contents of mannose and galactose were very similar in all cell walls, though differences were still statistically significant. Rhamnose and fucose were minor components (5-16 mg/g CW).

One marked difference between the cell walls was the arabinose content, particularly high in the cell walls from beet, while it was very low in the cell walls of kiwifruit (10 mg/g CW). The pectic substances of apple were more highly methylated (DM 82) than those of beet or kiwifruit, while acetyl groups were higher in beet, giving apparent degrees of acetylation (for pectins) > 100, and higher than reported in beet varieties used for sugar productions (DAc from 66 to 69 %) (Renard & Jarvis,

400 1999; Renard & Thibault, 1993). It should be mentioned that most cell wall polymers 401 can be acetylated, especially hemicelluloses and pectins (Gille & Pauly, 2012), and 402 that reporting acetylation relative only to galacturonic acid might lead to 403 overestimated degree of acetylation.

Cell walls can contain polyphenols or be contaminated by intracellular 404 polyphenols, and these patterns were different per species. All three native cell walls 405 contained some low amounts of lignin, with higher concentrations in the kiwifruit cell 406 407 wall. These were the only phenolic compounds detected in the kiwifruit cell wall. Beet cell walls contained ester-bound phenolic acids, primarily ferulic acid (7.0 mg/g 408 CW) lower than reported earlier (13-20 mg/g CW) (Renard & Jarvis, 1999; Renard & 409 Thibault, 1993). Ferulic acid is an intrinsic component of beet cell walls, where it is 410 bound to arabinans and galactan side chains of pectins (Fry, 1986). The native apple 411 412 cell wall was slightly contaminated by vacuolar procyanidins (0.26 mg/g CW) of high \overline{DP}_{n} (15). These procyanidins became non detectable in the modified apple cell walls 413 414 perhaps due to their removal with soluble polysaccharides as procyanidins have a high affinity, among polysaccharides, for pectins (Le Bourvellec, Bouchet, & Renard, 4152005). The AIS preparation used here includes a specific step for elimination of this 416 417 artefact, the efficiency of which was validated.

What about their common and specific responses after modification? For all cell walls, all the treatments led to a marked loss of arabinose and galacturonic acid, and by balance a relative increase in xylose, mannose and cellulose (Table. 1). Whichever

421 the treatment and the species, xylose and mannose from hemicelluloses and glucose from cellulose were not affected by acid hydrolysis nor β -elimination reactions, so 422 423 that their contents increased. The rhamnose and galactose contents were stable, so that their losses appeared to be close to the average cell wall loss. Intensity of loss of the 424 425 different sugars appeared to depend primarily on pH, then on species. The least 426 pronounced pectin depolymerization was observed at pH 3.5, that is, the neutral sugar, galacturonic acid, lignin contents were intermediate between values obtained in pH 427 2.0 and 6.0. This is a common response for all cell walls. It suggested that the 428 429 β-elimination reaction and acid hydrolysis occur simultaneously at pH 3.5, but both had a low intensity. This is consistent with Ella Missang et al. (2012) who reported the 430 431 composition of the cell wall material from cooked apricot at natural pH (c.a. 4.0) for 432 10 min did not change significantly, compared with the cell wall isolated from fresh apricot fruit. The same result was also observed in the pear cell walls (cooked at 85 $^{\circ}$ 433 C for 20 min) (Renard, 2005). Therefore, thermal processing at this pH can protect 434 435 fruits and vegetables by reducing the pectin degradation reaction rates by both β-elimination and hydrolysis. 436

At pH 2.0, the most marked difference concerned arabinose, while the galacturonic acid was mostly retained, in accordance to the order of sensitivity to hydrolysis of glycosidic linkages. Arabinose is in the furanose form in the cell walls, and bonds involving furanose sugars are particularly susceptible to acid hydrolysis (Fry, 1988). Moreover, significant specific responses were observed in the degree of arabinose loss in different cell walls at this pH. The percentages of arabinose loss for

443 AC2, BC2 and KCR2 were 59 %, 38 % and 30 %, respectively. Therefore, the arabinose in the apple cell walls was the most sensitive to acid hydrolysis. At this pH, 444 445 the content of ferulic acid in the beet cell walls was also relatively low, which is attributed to the degradation of arabinan side chains. Ferulic acid can participate in 446 intra-/inter- molecular crosslinking with arabinan chains (Morris & Ralet, 2012; 447 448 Wefers, Gmeiner, Tyl, & Bunzel, 2015) and limit beet texture loss (Waldron et al., 1997). Therefore a more acidic pH, by enhancing arabinan degradation and loss of 449 ferulic cross-links, might favour softening of beets. Li, Liu, Tu, Li, & Yan (2019) also 450 451 confirmed that the addition of ferulic acid led to better preservation of the cell wall structure of cooked radish. This may due to ferulic acid reaction with neutral sugar 452 side chains, preventing the leaching of pectins from the cell wall matrix. Compared 453 454 with the other two pH treatments and untreated cell walls, pH 2.0 processing increased the pectin linearity (GalA/Rha molar ratio) and decreased the RG-I 455 branching ((Ara+Gal)/Rha molar ratio) in all cell walls. 456

With regard to treatment at pH 6.0, the galacturonic acid content decreased 457 significantly after treatment in all cell walls, especially the kiwifruit cell walls, due to 458 459 β-elimination. The percentage of galacturonic acid loss for KCR6, AC6 and BC6 was 460 72 %, 42 % and 37 % in order. The galactose in AC6 and BC6 was not significantly 461 different from the untreated cell walls, while KCR6 lost 25 %. The common response under this condition is that the modified cell walls had the lowest pectin linearity and 462 the highest RG-I content. The cell walls also had significantly lower methanol and 463 slightly lower lignin contents. The acetyl groups of the cell walls were more stable in 464

apple and kiwifruit cell walls than beet cell walls, and also more stable than 465 methyl-esters during the processing (Broxterman, Picouet, & Schols, 2017), probably 466 467 because some O-acetyl-substituents were carried by other cell wall constituents (Gille & Pauly, 2012). Lower acetic acid content of beet cell walls after treatment at pH 6.0 468 469 may be due to the initial presence of acetylated pectins and loss during treatment. 470 Acid hydrolysis and β -elimination appeared to be common mechanisms that cause loss of neutral sugars, often from pectin side chains, and galacturonic acid, 471 respectively, but their effects were of different intensities. 472

473 This was confirmed by the ANOVA (Table 1): while the species was the most 474 significant factor, pH values and ripeness (for kiwifruit) had also significant effects. Only fucose was not significantly modified by treatment at different pHs, while the 475 476 effect on galactose and rhamnose was less marked than for all other parameters. The 477 interaction 'species × pH' influenced significantly acetic acid, methanol and neutral sugars such as arabinose, mannose, galactose and non-cellulosic glucose. This 478 confirmed the existence of common effects on galacturonic acid (and absence of 479 effect on cellulose) and more specific effects on pectic substituents and some neutral 480 481 sugars.

482 **3.2.4 Comparison of kiwifruit cell walls at two maturity stage**

After harvest, the kiwifruit underwent a marked softening. As is shown in Table 1, the neutral sugars, galacturonic acid, acetic acid, methanol and lignin contents were reduced from KCRs to KCOs, and the most relevant differences with maturity

concerned rhamnose, arabinose, galactose, glucose and galacturonic acid in 486 accordance with literature data on fruit softening: ripening involves hydrolysis of 487 neutral sugars from pectin side chains, depolymerization and increased solubilization 488 of pectins and hemicelluloses (Brummell, 2006). The degrees of methylation and 489 acetylation of pectins increased, signaling potential preferential degradation of the 490 less methylated and acetylated pectins during overripening. The cell walls of ripe 491 kiwifruit were more sensitive to the treatment at different pHs than that of overripe as 492 the main modifications had occurred during ripening. The interaction 'pH × maturity' 493 influenced significantly galactose. 494

Abbreviations: A, Apple; B, Beet; K,

501 Kiwifruit; P, solubilized polysaccharides; 2, pH 2.0; 3, pH 3.5; 6, pH 6.0; R, Ripe; O, Overripe.

502 **3.3 Characterization of solubilized polysaccharides**

503 Solubilized polysaccharides represented a minor part of the original cell walls, 504 with recoveries between 9.6 and 22% of the original cell walls, however, they were of 505 interest as indicators of involved mechanisms.

506 **3.3.1 Composition of the solubilized polysaccharides**

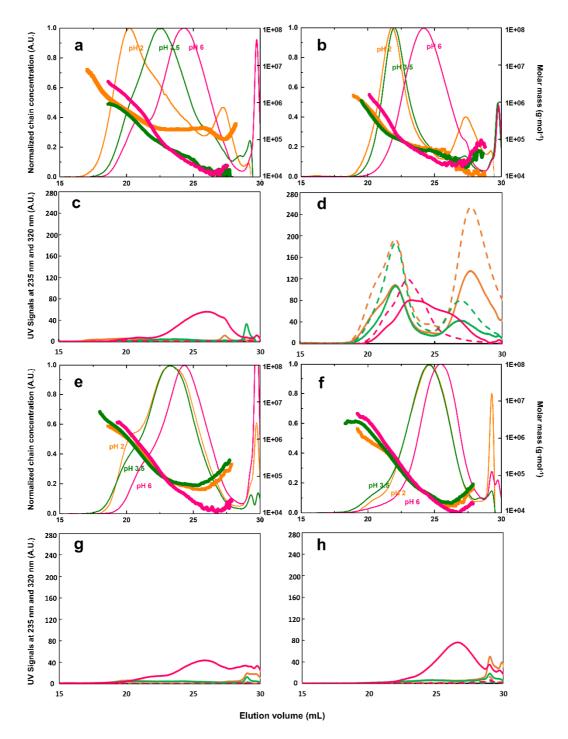

507 Similar to cell walls, solubilized polysaccharides (SP) from different cell walls or after treamtents at different pHs also showed both common and specific features. 508 509 Galacturonic acid was the main component in all SP, which were thus clearly mainly 510 of pectic nature, but significant differences were observed between the various pH 511 treatments and species (Table 2). Beet solubilized polysaccharides (BPs) had the 512 highest arabinose content with less xylose, galactose and galacturonic acid than apple 513 and kiwifruit. They were also the richest in glucose and acetic acid. Kiwifruit solubilized polysaccharides (KPs) had the highest galactose and glucose contents, and 514 515 apple solubilized polysaccharides (APs) the highest rhamnose and xylose contents. For all species, rhamnose content rose with increasing pH of the treatment. For apple 516 517 and beet cell walls treated at pH 6.0 SP were relatively enriched in galacturonic acid. 518 This could be linked to a larger amount of galacturonic acid solubilized from the cell 519 wall at pH 6.0. In addition, for APs and BPs, more acidic pH led to more extraction of 520 arabinose (Ara) and, for BPs, ferulic acid (FA), with a constant ratio of Ara/FA indicating that there was no specific extraction nor degradation of feruloylated 521 522 moieties during extraction. In the case of kiwifruit, the highest content of galacturonic

523 acid was at pH 3.5, and there were less differences as a function of pH. The Gal A/(Rha+Ara+Gal) ratio of KPs (from 3.9 to 10.9) was larger than APs (from 2.4 to 3.5) 524 525 and BPs (from 1.1 to 4.7) indicating KPs were less ramified. The DM showed differences between the various species and pH in Table 2. For the ANOVA result of 526 527 apple, beet, kiwifruit solubilized polysaccharides, arabinose, galactose, glucose, acetic 528 acid and ferulic acids were the most relevant compounds for differentiating pH values (Table 2). The interaction 'species \times pH' influenced significantly arabinose, acetic 529 530 acid and methanol.

Less arabinose, galactose and galacturonic acid were solubilized in SP from overripe kiwifruit cell walls, probably due to preliminary degradation of pectins by endogenous enzymes during overripening (Table 2). The most statistically significant differences that distinguished maturity were rhamnose, fucose, arabinose, xylose, mannose and galactose contents. The interaction 'pH × maturity' influenced significantly xylose and galactose (Table 2).

537 **3.3.2 Molar mass distribution of the solubilized polysaccharides**

538 HPSEC-MALLS chromatograms showed generally one main peak at 20-26 mL 539 with shoulders, representing high molar mass polymers, and a peak around 29-30 mL 540 which could be attributed to oligomers (Fig. 4a, b, e and f). With increasing pH value, 541 the main peaks of APs, BPs, KPRs and KPOs shifted to higher elution volumes 542 indicating a decrease in hydrodynamic volume, which was generally accompanied by 543 a decrease of the molar mass of the main fraction, M_p (Table 2).

c, d, g and h: ____ pH 2.0; ____ pH 3.5; ____ pH 6.0 represent UV signal at 235 nm and ____ pH
2.0; ____ pH 3.5; ____ pH 6.0 represent the UV signal at 320 nm.

551 APs had higher \overline{M}_{w} than BPs, KPRs and KPOs especially at pH 2.0 (AP2) (Table

2). The difference of molar mass and size between AP2 and AP3 (Table 2, Fig. 4a, b, e

and f) was much more marked than that of the three series of three pHs for beet and
kiwifruit, while all pectins extracted at pH 6.0 were clearly differentiated. Apple cell
walls thus appeared to react differently from beet and kiwifruit upon acidic treatment,
which was also coherent with the analysis of their infrared spectra (Fig. 3).

For AP2 and BP2, there were two distinct populations of SP, one major peaking at 557 20-22 mL with high molar masses, and a minor population peaking at 27-28 mL 558 corresponding to lower molar masses probably arising acid hydrolysis (Fig. 4a and b). 559 560 In BP2, these two fractions were also marked by relatively intense UV signals at 235 and 320 nm, which can be attributed to the presence of ferulic acid covalently 561 bounded to SP molecules (Fig. 4d). Moreover, the highest UV signals at 235 and 320 562 nm were found for low molar mass fractions of BP extracted at pH 2.0 (Fig. 4d), 563 564 mainly produced by acid hydrolysis. As ferulic acid is known to link preferentially to arabinose side chains of pectins, this may indicate that this low molar mass fraction is 565 richer in arabinans. The higher extraction of Ara observed at pH 2.0 for BP and AP 566 567 might then be due to higher hydrolysis of arabinan during acid extraction in line with the higher sensitivity of Ara-Ara linkages to acid hydrolysis (Renard et al., 1995). KPs 568 chromatograms exhibited one main peak with a shoulder at a lower elution volume 569 570 (24 mL) than APs and BPs, i.e. lower sized SP, but no peak at 27-28 mL, even for KPR2. Moreover, even if the shoulder in the main peak diminished when pH 571 increased, the molar mass observed for KPR2 and KPR3 were not significantly 572 different (Table 2), this indicates that very low acid hydrolysis occurred during 573 extraction at pH 2.0, probably because KPs contain fewer neutral sugars (Table 2). 574 35

AP2, BP2 and KPR2 exhibited a higher \overline{M}_{w} than their homologs extracted at higher pHs (Table 2), which suggested that larger SP were extracted at pH 2.0 even if a small amount of hydrolysis was observed as well. Interestingly, the specific extraction of high molar mass pectins from apple cell walls might explain the preferential industrial use of apples for pectin extraction, and imply the existence of specific, acid-labile bonds retaining pectins in apple cell walls.

581 After extraction at pH 6.0, all SP absorbed at 235 nm indicating β -elimination. 582 APs size and molar mass distributions were broader and tighter for the others (Fig. 4a, b, e and f). This suggests that apple SP were the most sensitive to pH treatment. This 583 may be attributed to the origin of the cell walls, i.e., to the intrinsic 3D cell wall 584 network and especially to the intermolecular interactions of the wall polysaccharides. 585 586 In particular, the pectin populations in the cell walls can interact with cellulose or hemicelluloses, with variation between different species (Broxterman & Schols, 2018). 587 These more or less strong interactions between the polysaccharides of the cell wall 588 589 drive the response to the different pH extraction conditions. For KPs in particular, when treatment pH increased the shoulder observed at 20 mL generally decreased. 590 591 These results are in agreement with previous observations on SP extraction by heating 592 at pH 6.0 which showed that the extraction led to one pectic fraction for beet and two pectic fractions for apple: one of high hydrodynamic volume, rich in neutral sugars, 593 and one of low hydrodynamic volume rich in galacturonic acid (Renard & Thibault, 594 1993). The main fraction of AP6 peaking at 3.2×10^4 g/mol might then be enriched in 595 galacturonic acid. In addition to the molar mass decrease, a signal at 235 nm was 596 36

597 obvious in the middle molecular size part of the chromatograms (elution volume around 24-27 mL) for all the SP extracted at pH 6.0 (Fig. 4c, d, g and h), indicating 598 599 the presence of unsaturated double bonds such as produced by β -elimination. As for APs, KPRs and KPOs extracted at pH 2.0 and pH 3.5 absorbances at 235 nm were 600 601 quite minors, this confirmed that the degradation of pectic fractions mainly occurred 602 through β-elimination at pH 6.0 for APs, KPRs and KPOs. Nevertheless, for BPs UV signals at 235 nm were present for all pHs: at pH 2.0 and 3.5 they closely followed 603 those at 320 nm, suggesting minor absorption from ferulic acid. At pH 6.0 however, 604 605 the two bands were not superimposable, with a shoulder at higher elution volumes for the signal at 235 nm, closely following the RI signal and again suggesting extraction 606 607 of homogalacturonan-rich pectins after β -elimination.

All SP from overripe kiwifruit were markedly smaller than their analogs from ripe kiwifruit (\overline{M}_w of 6.4 x 10⁴ g/mol and 1.53 x 10⁵ g/mol for KPO6 and KPR6 respectively, Table 2) confirming SP degradation during maturation as a result of endogeneous enzymic process (Matsumoto, Obara, & Luh, 1983). Nevertheless, the variation of molar mass observed between the extraction at different pHs occurred in the same proportions for KPs (Table 2) whatever their maturity.

614 **4 Conclusions**

We explored the interactions between cell wall structures, proxied by plant origin, and pH in a model system miming F&V processing. Cell wall modifications and polysaccharide solubilization occurring in commonly used fruits (apple and kiwifruit) 618 and vegetable (beet) revealed some common features but also some striking differences for the same pH. In all cases, pectins were clearly the polysaccharides the 619 620 most impacted, highlighted either from sugar loss in the modified cell walls or the composition of the solubilized polysaccharides. The acid treatment at pH 2.0 removed 621 622 the arabinan side chains but the solubilized polysaccharides had a higher 623 hydrodynamic volume, especially in apple. Galactose in kiwifruit cell walls was the most sensitive to boiling treatment, especially at pH 6.0. The main skeleton of pectins 624 was significantly degraded after treatments at pH 6.0 by β -elimination reaction, 625 626 leading to a higher extraction of smaller molecules, especially from kiwifruit cell walls. Under this condition, the molar mass of solubilized polysaccharides with more 627 628 unsaturated double bonds was the smallest. The effectiveness of the pH treatments on 629 different fruits and vegetables was different, and this was particularly marked for apple. 630

This study improved the understanding of structure/processing relationships and pointed out important differences concerning the behavior of individual species. This aspect means that each fruit or vegetable species should be regarded to have putatively some specificities in relation to their modified cell walls. The knowledge of such specificities in different natural sources can improve the quality of canned fruit and vegetable processing and open up prospects for their fine-tuning of functional characteristics.
