10 **Abstract**

11 Elastic properties are of particular interest during the development of tablets especially
12 for the definition of the formulation and of the process parameters. Impulse excitation,
13 which is used in several industrial fields to determine elastic properties of materials, is
14 presented in this article as a new fast and relatively cheap technology for the
15 determination of elastic constants of pharmaceutical tablets. This technique is based on
16 the detection of the natural resonance frequencies of solids. It was found in the present
17 work that, for tablets obtained using different products under different compaction
18 pressures, it was possible to detect clearly at least 3 resonance frequencies. Moreover,
19 the shape of the resonance peaks obtained in the spectrum could be a sign of the
20 viscoelastic nature of the tablet. With the two first resonance frequencies, it was
21 possible, under the assumption of isotropy, to calculate Young's modulus and Poisson's
22 ratio for each tablet using the methodology presented in the norm ASTM E1876-01. The
23 value obtained were found independent of the tablet size as expected, and were

24 consistent with those presented in the literature using other methodologies. Moreover,
25 using FEM simulation, it was found that the difference between the experimental value
26 of the third resonance frequency and the value obtained numerically was well correlated
27 with the expected anisotropy of the tablet. Impulse excitation could thus be an
28 interesting methodology to study tablet anisotropy.

29 **Keywords:** tablet; compression; elasticity; young's modulus; Poisson's ratio;
30 viscoelasticity; anisotropy

31 **1. Introduction**

32 The tablet is the most common pharmaceutical form. Nevertheless, the successful
33 development of a tablet involves a lot of critical steps from the formulation to the final
34 definition of the process parameters to ensure the desired quality attributes. During the
35 development, mechanical properties of tablets are important parameters. They are the
36 result of both the mechanical properties of the powders used and the process
37 parameters used to obtain the tablet. They play a key role in the success of tablet
38 production. Among these properties, elasticity is of particular importance. For example, it
39 is well-known that elastic properties are linked with the stress evolution during
40 compression (Diarra et al., 2018; Hiestand et al., 1977) and with adverse phenomena
41 like capping or chipping (Hiestand et al., 1977). A good measurement of tablet elasticity
42 is thus of particular interest. This article presents a new methodology for the
43 characterization of the elastic behavior of pharmaceutical tablets.

44 Elasticity can be characterized directly in the die (Cunningham et al., 2004; Hagelstein et
45 al., 2019; Mazel et al., 2012). In this case it might help to understand the stresses

46 evolution during the compression. This characterization is also useful for the calibration
47 of numerical models (Cunningham et al., 2004; Diarra et al., 2012). Another,
48 complementary approach is to characterize the elasticity of the final tablets. Several
49 methodologies have been presented in the literature to measure elastic moduli but also
50 to characterize the viscoelastic behavior or the elastic anisotropy. These methodologies
51 can be separated into two main categories.

52 First, classical mechanical tests are used to determine the quasi-static values of elastic
53 moduli. In most of the studies, only young's modulus is determined. For this purpose,
54 three or four points bending tests as well as indentation tests can be used (Bassam et
55 al., 1990; Busignies et al., 2006; Kuentz and Leuenberger, 1998). A torsion test on
56 specific geometries was also presented to obtain the shear modulus (Radebaugh et al.,
57 1989; Roberts et al., 1994). Using both moduli it is possible to calculate Poisson's ratio
58 (Roberts et al., 1994) but the results obtained showed surprising values of Poisson's
59 ratio that could even become negative (Mazel et al., 2012). So if the Young's moduli
60 reported in the literature using these techniques are consistent, Poisson's ratio values
61 are to be taken with caution.

62 The second category of tests study the dynamic elastic moduli. It must be noted that in
63 the case of viscoelastic materials, dynamic elastic moduli might differ from quasi-static
64 ones. This can be performed by measuring wave propagation in the tablets using either
65 ultrasonic (Akseli et al., 2009b, 2009a) or photoacoustic waves (Ketolainen et al., 1995).
66 These methodologies can make it possible to determine both Young's modulus and
67 shear modulus and to deduce Poisson's ratio. In the case of Photoacoustic evaluation, a
68 large dispersion is obtained for Poisson's ratio (Ketolainen et al., 1995). Moreover, in the

69 case of ultrasound, anisotropy can also be assessed (Akseli et al., 2009b).
70 Nevertheless, the technique is quite expensive and complicated to use which might
71 explain why only few articles have been published on the subject even if the technique is
72 used for more than 10 years.

73 Another possibility is the use of dynamic mechanical analysis (DMA) to measure both
74 Young and shear moduli as a function of the frequency (Hancock et al., 2001;
75 Radebaugh et al., 1989). Nevertheless, it is the author experience that due to the small
76 size and relatively high values of elastic moduli, pharmaceutical tablets are difficult to
77 test on commercial apparatus. This might explains the strangely low values for young's
78 moduli obtained in some publications (Ascani et al., 2019). Finally, Maranzano et al.
79 presented an interesting technique using drop tests on a piezo electric force sensor
80 (Maranzano et al., 2013). Thanks to the transformation of the force signal obtained, it is
81 possible to calculate Poisson's ratio and young's modulus. If this technique is very
82 interesting, the results show large errors bar on young's modulus and values of
83 Poisson's ratio that are sometimes higher than 0.5, which is physically impossible, at
84 least for isotropic tablets as supposed in the article.

85 Impulse excitation technique, is used from a long time in different scientific fields to
86 characterize the elastic properties of materials. It can be applied to a lot of different
87 materials like ceramics or composites (Swarnakar et al., 2009; Tognana et al., 2010).
88 The principle is to measure the natural resonance frequencies of a material. These
89 frequencies are linked with the dynamic elastic properties of the material and with the
90 geometry of the sample used for the characterization. These relations are given for
91 example in the norm ASTM E1876-01. Excitation of the resonance frequencies is

92 achieved by submitting the sample to a very short impact. This technique is easy to
93 implement and relatively cheap compared to others (like ultrasonic measurement for
94 example). To our knowledge, it was never applied to pharmaceutical tablets, but it could
95 constitute an easy methodology to study the elastic properties of tablets. The aim of this
96 article is thus to study the applicability of this technique to pharmaceutical tablets and to
97 give a first overlook of the possibilities offered in terms of characterization. It thus
98 constitutes a first step in the development of this technique in the pharmaceutical field.

99 **2. Materials and method**

100 **2.1. Powders**

101 Four classical pharmaceutical excipients were used in this study: anhydrous lactose
102 (Alac) (Duralac H, Meggle, Wasserburg, Germany), Lactose monohydrate (MLac)
103 (Excipress 150Gr, Armor Pharma, France), Anhydrous calcium phosphate (ACP)
104 (Anhydrous Emcompress, JRS pharma, Rosenberg, Germany) and microcrystalline
105 cellulose (MCC) (Vivapur 12, JRS pharma, Rosenberg, Germany). To perform the
106 compaction experiments, MLac, MCC and Alac were mixed with 1% (w/w) of
107 magnesium stearate (Cooper, Melun, France) to minimize the frictions in the die. ACP
108 was mixed with 2% Magnesium stearate. The blending was performed at 49 rpm for 5
109 min using a turbula mixer (Type T2C, Willy A Bachofen, Muttenz, Switzerland).

110 **2.2. Tablet manufacturing**

111 All tablets were manufactured on a compaction simulator Styl'One Evolution
112 (Medelpharm, Beynost, France). This device is a single station instrumented tableting
113 machine. It is equipped with force sensors (strain gauges) on both punches and on the

114 die wall, and the displacements of the punches are monitored using incremental
115 sensors. It is equipped with a separate engine for each punch. Punches can thus be
116 moved independently. Euro B flat faced punches with a diameter of 16 mm were used
117 for all the products and Euro B flat faced punches with a diameter of 11.28 mm were
118 used to produce a supplementary group of MCC tablets. For each product, three
119 compression pressures were used: 100, 150 and 200 MPa. Filling height was modified
120 in each case to obtain a final tablet thickness of 3 mm for the 16 mm tablets and of 2
121 mm for 11.28 mm tablets. This selection was made to maintain a thickness to radius
122 ratio below 0.5 as recommended by the norm ASTM E1876-01. For each condition
123 (product/pressure/size) 5 tablets were manufactured and analyzed using the impulse
124 excitation method.

125 **2.3. Impulse Excitation method setup**

126 The signal for the impulse excitation method was acquired using a microphone MM310
127 (Microtech Gefell GmbH, Gefell, Germany). This device makes it possible to measure
128 frequencies from 20 Hz to 100 kHz. The data acquisition system was a DEWE-43
129 coupled with the software Dewesoft X3 (Dewesoft, Trbovlje, Slovenia). Acquisition
130 frequency was set to 200kHz and as a consequence the maximal detectable frequency
131 was 78.1 kHz. Time domain amplitude signal was converted into a frequency domain
132 signal to measure the resonance frequencies using a fast Fourier transform (FFT)
133 algorithm. A Blackman window with 4069 points was used. The final frequency
134 resolution was 25Hz. A complete description of the experimental procedure is given
135 below in the results section.

136

137 **2.4. Numerical method**

138 Numerical calculation of the resonance frequencies of tablets was performed using
139 Finite element method (FEM). The FEM modelling was performed using Abaqus®
140 software (Abaqus® Standard 6.13, Dassault Systèmes, Vélizy-Villacoublay, France). The
141 Lanczos method was used in conjunction with isotropic linear elastic properties as
142 proposed in the literature (Akseli and Cetinkaya, 2008). This method is already
143 implemented in the Abaqus code.

144 **3. Results and discussion**

145 **3.1. Measurement of resonance frequency**

146 The methodology developed in this article was based on the norm ASTM E1876-01.
147 Nevertheless, due to the small size of pharmaceutical compacts, some improvements
148 were necessary to obtain a good measurement of the vibration frequencies.

149 The principle of the technique is to submit the tablet to an excitation and to record the
150 response of the tablet in terms of vibrational waves (sound or ultrasound). In the norm
151 ASTM E1876-01, the excitation is given by an impulser that will impact the sample.
152 Moreover, a support is also needed to set the tablet. Another common alternative is to
153 set the tablet on a foam. Preliminary results using this methodology showed that for
154 some products (especially MCC in the present case), the resonance frequencies could
155 not be measured.

156 In the case of pharmaceutical tablets, we found that it was suitable to drop the tablet,
157 from a height around 5 cm, on a hard surface (ceramic) and to record the sound
158 promoted by the shock between the tablet and the hard surface. Using this

159 methodology, it was possible to measure the resonance frequencies of all the products
160 compressed at all the pressure levels used in this study. Different ways of dropping the
161 tablet (on the band, on the surface, on the edge) were tested. Recorded spectra
162 indicated that resonance frequency peaks were better recorded when the tablet was
163 dropped on the band. Finally, in the present methodology, noise can be obtained in the
164 sound range especially below 15kHz. As a consequence, resonance frequency in this
165 range could be difficult to measure.

166 Figure 1 shows examples of frequency spectra obtained for the different products, using
167 the tablets obtained under a compaction pressure of 150 MPa. For all the products
168 vibration frequencies are clearly seen on the spectra. Depending on the product, the
169 number of frequencies detected ranged from 3 to 7. For each tablet, at least five spectra
170 were recorded. By comparing the spectra, it was found that, the variation of the
171 frequency from one spectrum to the other, was never higher than 0.1 kHz. The norm
172 ASTM E1876-01 only considers the two lower frequencies (F_1 and F_2 in table 1) for the
173 calculation of Young's modulus and Poisson's ratio. Nevertheless, the other frequencies
174 can also be of interest as it will be shown below. From the graph, it can be seen that
175 each product has a specific set of vibration frequencies that corresponds to its own
176 elastic properties. The methodology makes it thus possible to differentiate the different
177 products one from the other.

178 In the case of MCC, two tablet sizes were used. The resonance frequencies of a tablet,
179 depends on its elastic properties but also on its dimension. Reducing the diameter of the
180 tablet promotes a shift of the resonance frequency towards higher values as it can be
181 observed in Figure 1. This can be interesting in the cases where the vibration

182 frequencies are very low and could thus be mixed with the noise present below 15kHz.
183 Depending on the elastic properties of the studied product, tablet shape can thus be
184 varied in order to obtain correctly measurable frequencies.

185 Finally, another interesting point is the shape of the peaks obtained for the different
186 products. If we consider the first peak of the spectra, very narrow peaks are obtained for
187 ACP, Alac and Mlac. On the contrary, MCC presents much broader peaks. The width of
188 the peak is in fact linked with the viscoelastic properties of a product (Bernard et al.,
189 2014). Indeed, viscoelasticity corresponds, in terms of vibration, to a damping factor. In
190 general, for oscillators, the result of damping is an increase of the width of the
191 resonance peak. This is exactly what is observed in Figure 1. Whereas ACP, Mlac and
192 Alac are not considered as viscoelastic, MCC is a viscoelastic product (Hancock et al.,
193 2001). This explains the larger peaks obtained for this product. The damping due to
194 viscoelasticity could also explain why only 3 frequencies are obtained for MCC contrary
195 to the other products. For the moment, this observation is not quantitative and work is
196 necessary to develop this aspect. But it indicates that further development could make it
197 possible to use, in the future, Impulse excitation technique for the characterization of the
198 viscoelasticity of pharmaceutical tablets.

199 **3.2. Elastic constant determination**

200 As shown before, the methodology developed makes it possible to detect the two lower
201 frequencies of vibration of pharmaceutical tablets. According to the norm ASTM E1876-
202 01, Young's modulus and Poisson's ration could be determined for each tablet using
203 these two frequencies. The calculation was thus made for all the tablets according to the

204 recommendation of the norm. The following paragraphs only give a short summary of
205 the methodology. A complete development can be found in the norm ASTM E1876-01.

206 Derivation of the elastic moduli was performed in two steps. First, thanks to the ratio
207 between the two resonance frequencies, Poisson's ratio could be determined using a
208 table given in the norm that accounts also for the tablet dimensions. Once Poisson's
209 ratio is determined, other tables, given in the norm ASTM E1876-01, made it possible to
210 determine two constants, K_1 and K_2 , which were used to calculate Young's modulus. In
211 fact, Young's modulus could be calculated from any of the two frequencies using the
212 following equation:

$$213 \quad E_i = \frac{37.6991 f_i^2 D^2 m (1 - \nu^2)}{K_i^2 t^3}$$

214 were $i=1$ or 2 , f_i is the i^{th} resonance frequency, ν is the Poisson's ratio and D , m and t
215 are respectively the mass, the diameter and the thickness of the tablet. As
216 recommended in the norm, Young's modulus was determined using the two frequencies
217 and the mean of the two values was finally considered. It must be noted that for round
218 tablets, the use of tables generates an imprecision in the results. To obtain results as
219 precise as possible, 2D curve fitting of the tables was performed using the software
220 Origin 7.5 (Originlab, Northhampton, USA).

221 Young's moduli and Poisson's ratios for all the tablets as a function of the porosity are
222 presented in Figure 2. As mentioned previously, for each condition a batch of five tablets
223 was analyzed. The results of all the tablets are presented in figure 2. As it can be seen
224 the dispersion of the results for each batch is quite small, especially for Young's
225 modulus. From a more quantitative point of view, the standard deviation was calculated

226 for each batch. It was found that it was always below 0.06 GPa for Young's modulus and
227 0.01 for Poisson's ratio. The reproducibility is thus good and comparable with the one
228 obtained with other techniques (Mazel et al., 2012).

229 The results give trends as a function of the porosity that are similar to those presented in
230 the literature. Young's modulus and Poisson's ratio are increasing with a decreasing
231 porosity. Another interesting point is the comparison for MCC between the two sizes of
232 tablets. For both sets, the value of Young's modulus and Poisson's ratio are well
233 superimposed. This constitute an important confirmation that the methodology can
234 indeed be applied consistently to pharmaceutical tablets.

235 Concerning, the numerical values, as the moduli are obtained out of die, it is
236 complicated to compare the obtained values with studies performed in die (Cunningham
237 et al., 2004; Mazel et al., 2012). The ejection process could indeed promote large
238 modifications of the tablet structure. Comparison should thus be limited to studies that
239 performed out of die characterization of tablets.

240 For Young's modulus, comparison can be made with studies using three point bending
241 tests (Bassam et al., 1990; Busignies et al., 2006, 2004). Nevertheless, the present
242 methodology measures the dynamic elastic moduli. In a case of a viscoelastic product,
243 like MCC, the dynamic values could be higher than the quasi-static values measured in
244 three point bending for example. The values shown in Figure 2 are in the same order of
245 magnitude than those presented for example by Busignies et al.(Busignies et al., 2006).
246 Larger values for anhydrous lactose than for lactose monohydrate were also reported in
247 the literature (Busignies et al., 2004). Globally, Young's modulus values are thus in the
248 expected range, considering also the variability of the results presented in the literature.

249 For Poisson's ratio, as mentioned in the introduction, it is difficult to find experimental
250 values to compare our results. The values presented in Figure 2 are rather low
251 compared to those presented by Maranzano et al.(Maranzano et al., 2013) which are, as
252 said before, to be taken with caution. Nevertheless, the trend as a function of the
253 porosity seems to be consistent and the dispersion of the results is quite small.

254 To conclude on this part, the methodology makes it possible to obtain reproducible
255 results in terms of elastic moduli. Moreover, the results are not affected by the size of
256 the sample used.

257 **3.3. Effect of anisotropy**

258 In the application of the norm ASTM E1876-01, it is supposed that the solid is isotropic.
259 In the case of pharmaceutical tablets, this hypothesis is questionable as reported by
260 several authors (Akseli et al., 2009b; Galen and Zavaliangos, 2005; Porion et al., 2009).
261 This anisotropy should nevertheless depend on the product. It was shown for example
262 that MCC tablets are more anisotropic than ACP tablets (Porion et al., 2009). If the
263 anisotropy of the tablet is important, the previously determined moduli should then be
264 considered as apparent isotropic moduli, as in the case of the elastic moduli measured
265 in die during compression.

266 The previous methodology only used the two first frequencies. Nevertheless, it was
267 shown in Figure 1 that at least 3 frequencies could be determined for all products. The
268 vibration modes corresponding to these three first frequencies can be seen in Figure 3
269 (FEM calculation). Knowing the elastic properties, it is possible to predict all the
270 resonance frequencies of a solid, for example using FEM simulation. So if the elastic

271 constants determined previously are correct, all the frequencies of the spectrum should
272 be predicted correctly using FEM simulation and not only the two first ones.

273 The test was performed using the third frequency of the spectrum that can be seen for
274 all the products. First the elastic parameters obtained previously were entered in the
275 simulation to calculate the two first frequencies. It was found necessary to slightly adjust
276 these elastic parameters to obtain exactly the experimental frequencies by numerical
277 simulation. This is understandable as the determination of Poisson's ratio, K_1 and K_2 are
278 made using tables and not analytical equations. This method promotes some
279 uncertainties on the final results. Once the final elastic moduli obtained, the three first
280 frequencies could be obtained in the simulation. This methodology was applied for one
281 tablet obtained under 150 MPa for each product. The comparison between the
282 experimental and numerical frequencies is given in table 1.

283 As mentioned above, experiments showed that the error on the measurement of a
284 frequency in the spectrum was around 0.1 kHz. Any difference below this value should
285 thus be considered as insignificant. The two first frequencies are well predicted, which
286 means the elastic parameters are correctly set in the simulation. On the contrary, the
287 quality of prediction of the third frequency depends on the product. For ACP, the third
288 frequency is well predicted whereas this prediction is not so good for Alac and Mlac and
289 is even worse for MCC. It is known from the literature that MCC is strongly anisotropic
290 (Akseli et al., 2009b; Galen and Zavaliangos, 2005; Porion et al., 2009). Mlac is also
291 known to present some anisotropy but to a smaller extend than MCC (Akseli et al.,
292 2009b). Studies on ACP showed isotropy in terms of porous network (Porion et al.,

293 2009). There is thus a good correlation between ΔF_3 and the expected anisotropic
294 behavior.

295 This result has two main consequences. In the case of anisotropic tablets, the
296 methodology developed in section 3.2 gives apparent isotropic elastic constant which
297 might not represent exactly the true elastic constant values. Second, the methodology
298 presented in the present paper could be an interesting mean to study the anisotropy of
299 tablets in terms of elastic properties. Further work is needed to develop the
300 characterization of anisotropic properties using this technique.

301 **4. Conclusion**

302 As shown in this paper, impulse excitation can be applied to pharmaceutical tablets to
303 determine their resonance frequencies. For all the product studied, at least 3 resonance
304 frequencies could be detected. Moreover, depending on the product, the size of the
305 tablet could be adjusted to obtain the frequencies in the measuring range.

306 The shape of the peaks can give some information on the viscoelastic nature of the
307 studied tablet. Indeed, viscoelastic products give much broader peaks in the spectrum.
308 This information is for the moment very qualitative, nevertheless, developments could be
309 made to use impact excitation to study viscoelasticity.

310 Using the two first frequencies of the spectrum, it is possible to calculate the elastic
311 properties of the tablet, under the assumption of isotropy, using for example the ASTM
312 norm E1876-01. Young's modulus and Poisson's ratio were obtained for tablets made of
313 several products and manufactured under several pressure points. The values for
314 young's moduli were coherent with published data. Values for Poisson's ratio were low

315 but there are not enough data published on this topic to make a useful comparison.

316 Moreover, the size of the tablet had no influence on the value of the moduli.

317 Finally, by looking at the third frequency of the spectrum and by comparing it with

318 numerical modelling results, we found that differences between measured and

319 calculated values could be a sign of tablet anisotropy. These results are very

320 preliminary, but impulse excitation could be an interesting technique to study the

321 anisotropy in the elastic properties of tablets.

Table 1: comparison between experimental (exp) and numerical (FEM) frequencies for tablets obtained under 150MPa. F_1 , F_2 and F_3 correspond to the three first resonance frequencies in ascending order. ΔF_i correspond to the absolute difference between experimental and numerical value for the frequency F_i .

Product	F_1 (kHz)			F_2 (kHz)			F_3 (kHz)		
	Exp	FEM	ΔF_1	Exp	FEM	ΔF_2	Exp	FEM	ΔF_3
