Abstract

Chlorinated paraffins (CPs), or polychlorinated *n*-alkanes, form a complex family of chemicals as they exist as mixtures of several thousands of isomers. To facilitate their classification, they are subdivided into short-chains (C_{10}-C_{13}, SCCPs), medium-chains (C_{14}-C_{17}, MCCPs), and long-chains ($C_{\geq 18}$, LCCPs) and further subdivided according to their chlorination degree. Until recently, the most common strategy implemented for their analysis was GC-ECNI-LRMS, with the main disadvantage being the high dependence of the response to the chlorination degree and the incapability of analysing LCCPs. In this work, we developed a method based on liquid chromatography coupled with electrospray ionisation-Orbitrap mass spectrometry (LC-ESI-HRMS) to expand the analysis capabilities of CPs. Although the different physico-chemical properties of CPs have led to compromises on the choice of analytical parameters, the addition of a mixture of DCM/ACN post-column with appropriate LC-ESI(-)-HRMS parameters enabled optimal and simultaneous detection of SCCPs, MCCPs and LCCPs from 10 to 36 carbons in one single injection. The combination of both the optimised LC-ESI parameters and the high resolution of the mass spectrometer (R = 140,000 @200 *m/z*) allowed separation of CPs signals of interest from unwanted halogenated ones, leading to minimum interferences in the detection. The optimised method was then successfully applied to the characterization of three types of vegetable oil, which were mostly contaminated with MCCPs. Additionally, the implementation of the LC-HRMS strategy enabled the identification of highly chlorinated LCCPs in edible oil for the first time at dozens of ng.g^{-1} lw, which demonstrates the need of such comprehensive methods to expand the knowledge about CPs occurrence in food and environmental matrices.

1. Introduction

Chlorinated paraffins (CPs) are a family of high production volume chemicals, whose chemical formula is $C_nH_{2n+2-x}Cl_x$ (n ∈ ⟦10,30⟧, %Cl = 40-70% *w/w*)[1]. The magnitude of this family leads to a wide variety of chemical properties, and hence numerous industrial applications such as cutting oil, lubricants, plasticizers and flame retardants. It is usual to distinguish short-chain (SCCP, C_{10}-C_{13}) from medium-chain (MCCPs, C_{14}-C_{17}) and long-chain (LCCPs, $C_{\geq 18}$) CPs. Their production started in the 1930s, but has been drastically growing in the past few decades, mainly due to the entry of China in the global production in the 2000s[2]. Nowadays, the worldwide production of CPs is estimated to be >1 million tons a year, which surpasses the cumulative former production volume of polychlorinated biphenyls[1,2]. Among CPs, SCCPs have received the highest attention, partly due to their toxicity towards aquatic life and mammals[3,4]. SCCPs have thus been registered as Persistent Organic Pollutants (POPs) in the Stockholm convention since 2017[5–7]. As a result of those restrictions, SCCPs are being replaced by MCCPs in almost all their applications, which consequently leads to a shift in environmental occurrences from SCCPs to MCCPs[8]. As MCCPs are under increasing scrutiny, it is besides expected that a shift from MCCPs to LCCPs will occur in the next decades for some applications[9,10], further increasing the complexity of CPs mixtures found in environmental and food matrices. Although CPs are now well known, studies on their toxicity and their occurrence, especially on MCCPs and LCCPs, are still scarce and are required to characterise fully the risk associated to CP exposure.

The lack of knowledge on SCCPs, MCCPs and especially on LCCPs occurrence arises from the high complexity of the compounds family. Indeed, the substitution of a hydrogen by a chlorine during the synthesis is not selective, leading to wide possibilities of constitutional isomers. For instance, more than 7000[11] isomers have been reported as constituting a SCCP technical mixture, and the complexity increases with the chain length. To date, complete separation between homologues groups (i.e. between two chemical formulas) by chromatographic techniques is considered a huge issue, and only homologue-specific identification and sum SCCPs, MCCPs or LCCPs quantification is possible[12,13]. Until the last decade, the predominant technique used to characterize CPs was gas chromatography coupled

3

65 to electron capture negative ionisation-low resolution mass spectrometry (GC-ECNI-LRMS)[14] for its

66 capability of analysing CPs homologues with relatively high sensitivity[15,16]. However, although it is

67 considered a soft ionisation inducing limited fragmentation compared to electron impact, numerous

68 ions are formed in the source such as $[M - Cl]^-$, $[M - HCl]^-$, $[M + Cl]^-$, $[HCl_2]^-$, and $[Cl_2]^{-}$ [17], further

69 increasing the complexity of the spectra. This leads to severe mass interferences and complex

70 algorithms must be used to circumvent those interferences when using low resolution mass

71 spectrometry (ex. $[C_{10}H_{14}Cl_8 - Cl]^-$, m/z 380.8886 and $[C_{10}H_{16}Cl_6 + Cl]^-$, m/z 380.9072)[18]. Moreover, as

72 the ionisation efficiency depends on the chlorine content of the molecules, the quantification can vary

73 drastically depending on the chlorination of the analytical standards used[19].

74 During the past decade, the research dedicated to CPs analysis has grown significantly, mainly relying

75 on recent technological innovations. Notably, the first CPs separation by two-dimensional gas

76 chromatography was attempted in 2005 by Korytar et al.[20], and then Xia et al. managed to improve

77 the separation of SCCPs by changing stationary phases and optimisation of GC parameters[21]. However,

78 the volatility of CPs decreasing with increasing chain length, GC analysis is limited to SCCPs and MCCPs

79 analysis. Hence, alternative comprehensive analytical methods such as direct introduction or liquid

80 chromatography (LC) prior to MS analysis should be developed to study the LCCPs occurrence. The

81 main difficulty related to such methods is the requirement of atmospheric pressure ionisation (API)

82 sources, mainly electrospray ionisation (ESI), which is not suitable for nonpolar compounds such as

83 CPs. However, Zencak and Oehme[22] demonstrated that adding a modifier to the mobile phase could

84 enhance the formation of adducts, and thus facilitate LC-MS analysis. Since then, several strategies

85 have been suggested. Bogdal et al.[23] proposed a chlorine-enhanced method by direct-introduction into

86 an atmospheric pressure chemical ionisation source and analysis with a quadrupole time-of-flight high-

87 resolution mass spectrometry (APCI-qTOF-HRMS) operated in full scan mode, with the advantage of

88 being extremely fast (<1 min). Later, Li et al.[24] used liquid chromatography coupled with chlorine-

89 enhanced electrospray ionisation-quadrupole time-of-flight mass spectrometry (ESI-qTOF-HRMS), and

90 compared their observations with an APCI-Orbitrap approach[25], with the interesting findings that LC

91 coupling improved both the sensitivity and selectivity of the detection compared to direct

92 introduction. In these cases, post-acquisition data-treatment of CPs signals from HRMS data sets

93 remains highly demanding. More recently, Yuan et al.[26] developed a bromide-anion attachment

94 APCI-MS method (Br-APCI-qTOF-MS), which simplified the spectra as only [M + Br]$^-$ anions are

95 observed, improving thus the selectivity of the method.

96 Although these recent analytical strategies allow detecting LCCPs as well as SCCPs and MCCPs, their

97 robustness has not been fully assessed. Indeed, although recent interlaboratory studies were

98 performed for SCCPs and MCCPs[12,13] and showed improvement of the interlaboratory variabilities,

99 results were mostly reported for GC-MS instruments with the exception of a few laboratories using

100 APCI-qTOF-MS and LC-ESI-HRMS. Moreover, investigations are still on-going to understand the sources

101 of the reported variabilities (CVs up to 137%), with one major reason being undeniably the challenges

102 of CPs quantification. Indeed, because of the lack of labelled CPs standards, scientists are forced to

103 develop   alternatives   to   classical   quantification   strategies,   which   can   induce   strong

104 over/underestimations of the concentrations[27,28].

105 We believe that one way of improving the robustness and comparability of the analytical methods is

106 to get information on the differences of ionisation depending on the chain length and chlorination

107 degree of CP standards. Thus, in this study, we take advantage of both the LC-Orbitrap-HRMS

108 instrumentation, which allows detection of CPs with no mass interference, and an in-house software

109 to perform semi-automatic post-acquisition data-treatment, to deeply investigate the behaviour of

110 several ions of CPs in ESI and APCI, depending on the chlorination degree and chain length of the

111 homologue groups. In light of those results, we propose an optimised chlorine-enhanced LC-ESI-HRMS

112 method for comprehensive analysis of CP patterns in environmental and biota samples.

113

114 **2. Material and methods**

115 *2.1. Chemicals*

116 Hexane, dichloromethane (DCM) and magnesium silicate (Florisil) were purchased from LGC

117 Promochem® (Picograde quality, Wesel, Germany). Sulphuric acid (98%) was purchased from Panreac

118 (Barcelona, Spain). Silica gel (70/230 mesh, Fluka, Buchs, Switzerland), LC-MS grade water and

119 acetonitrile (ACN), ammonium acetate, chloroform, dibromomethane and diodomethane were

120 provided by Merck (Darmstadt, Germany). Bromoform was purchased from Fisher chemical.

121 In order to investigate the behaviour of CPs according to their chain length and chlorine content, a *CP*

122 *standard mixture* was prepared by combining four technical standards from AccuStandard Inc. (New

123 Haven, CT, USA) at equal proportions, including Chlorowax™ 500C (SCCPs, low chlorine content, *SCCPs*

124 *Low %Cl*), Paroil™ 179-HV (SCCP, high chlorine content, *SCCPs High %Cl*), Unichlor™ 40-90 (LCCP, low

125 chlorine content, *LCCPs Low %Cl*) and CPW-100 (LCCP, high chlorine content, *LCCPs High %Cl*)

126 (Figure 1). Additionally, a MCCPs technical mixture produced by a Chinese company and kindly

127 provided by the EMPA institute (Dübendorf, Switzerland), referred to as "I-42", was used for semi-

128 quantification in the oil samples. A mixture of chlorinated contaminants including lindane, endosulfan

129 sulfate, chlordecone hydrate and nonachlor was purchased from Cambridge Isotope Laboratories

130 (Tewksbury, USA), tetrabromobisphenal A (TBBPA) and ^{13}C- and d_{18}-hexabromocyclododecane (^{13}C-

131 and d_{18}-HBCDD) from Wellington Laboratories (Ontario, Canada) and octachlorobornane from LGC

132 standards (Wesel, Germany).

133

134 *2.2. Sample preparation*

135 A pool of fish muscles (pickerel, trout, sardine, carp and arctic char) available from previous studies

136 was lyophilised and extracted by Pressurised Liquid Extraction (SpeedExtractor E-914, Büchi,

137 Switzerland) with a mixture of toluene/acetone (7:3, *v/v*) pending three static cycles. The extract was

138 split prior to purification steps.

139 Clean-up of the fish extracts and vegetable oils were performed by loading about 1 g of fat on a first

140 column packed with 20 g of neutral and 40 g of acidic (44% H_2SO_4) silica gel. Elution was performed

141 with 120 mL of a mixture of DCM/Hexane (1:1, *v/v*). After reconstitution in 1 mL of hexane, the extracts

142 were further purified with 6 g of deactivated Florisil® (3% H_2O). Rinsing was achieved with 20 mL of

143 hexane, and then elution was performed with 20 mL of DCM. The extracts were reconstituted in 50 µL

144 of acetonitrile and stored at -20 °C until analysis.

145 For instrumental optimisation purposes (cf. §3.3), the fish extracts were spiked with the *CP standard*

146 *mixture* at a final concentration of 10 ng.µL^{-1} per standard. For semi-quantification of vegetable oils,

147 10 ng of ^{13}C-and d$_{18}$-HBCDD were added in the samples before clean-up and before final extraction

148 reconstitution, as internal and external standards, respectively.

149

150 *2.3. Data acquisition*

151 Analytical standards and extracts were analysed with an UltiMate 3000 UHPLC pumping system

152 coupled to a Q-Exactive mass spectrometer fitted with either a Heated ElectroSpray (HESI) or an

153 Atmospheric Pressure Chemical Ionisation (APCI) source (Thermo Fischer Scientific, San José, CA, USA).

154 The sample injection volume was 5 µL, and chromatographic separation was achieved using reversed

155 phase chromatography on a Hypersil Gold analytical column (100 mm × 2.1 mm, 1.9 µm) (Thermo

156 Fischer Scientific) maintained at 30 °C. Mobile phase consisted in 70% to 100% ACN in water (6 min

157 gradient, and then 6 min isocratic at 100% ACN) at a flow rate of 0.4 µL.min^{-1}. The modifier added

158 post-column will be discussed later.

159 The source parameters and monitored ions will also be discussed hereafter. Briefly, the ionisation of

160 CPs was performed with an ESI or APCI probe in negative acquisition mode with a voltage of 2.5 kV.

161 The sheath gas and the auxiliary gas flow rates were 50 and 5 arbitrary units (AU), respectively. The

162 capillary temperature, the probe temperature as well as the optical lenses were modified to achieve

163 the highest efficiency of the monitored ions. HRMS data were acquired in full scan mode over the *m/z*

164 range [300-1500], with the AGC target set at 5.10^5 and at a resolving power set at 140,000 full width

165 at half maximum at *m/z* 200.

166

167 *2.4. Automatic data-treatment*

168   Raw LC-HRMS data (*raw*) were converted to an open format (*mzXML*) using the open access *msConvert*

169   software (ProteoWizard) through the open source programming R environment. Theoretical isotopic

170   patterns of selected ions for all CP homologue groups within C_8-C_{36} chain length and Cl_4-Cl_{30} chlorine

171   number were computed through the open R environment using the *isopattern*, *envelope* and *vdetect*

172   functions from the *enviPat* package[29]. The targeted homologues list started from C_8 in order to identify

173   potentially occurring "very-short" CPs[30], and homologue groups with $n_{Cl} > n_C+2$ were excluded as

174   substitution of 2 chlorines per carbon is unlikely from the synthesis mechanism[31]. A list of *m/z* features

175   (n = 1146) corresponding to the two most intense ions (quantifier & qualifier) from each homologue

176   group was compiled (Table S1). The data were computed in the centroid mode with R=140,000@200

177   as resolution and threshold = 0.001. Their corresponding intensities were then computed in the R

178   environment using the *rawEIC* function from *xcms* package[32] to generate Extracted Ion

179   Chromatograms at ± 5 ppm tolerance according to the sequence and the *trapz* function from the

180   *pracma* package[33] to integrate areas within 2-14 min retention time (RT) range. As the LC provides only

181   limited separation of CPs, the RTs were not used as identification criteria. However, only homologue

182   groups featuring an area >1 000 000 AU and complying 20% tolerance compared to the theoretical ion

183   ratio between the two most intense ions of the isotopic profile were considered. Intensities were then

184   normalised to total homologue isotopic patterns to correct for the isotopic contribution of the

185   quantifier ion. For comparison purposes during the instrumental development, the homologue peak

186   areas were summed according to the four standards from the *CP standard mixture*.

187   For interferences considerations, theoretical *m/z* values of all the isotopologues of the $[M + Cl]^-$,

188    $[M - H]^-$, and $[M + C_2H_3O_2]^-$ ions were computed for each homologue from C_8 to C_{36} and Cl_4 to Cl_{n+2} in

189   the *m/z* [300-1500] range (according to *enviPat 2.2*, Table S2). Then, the mass-to-charge ratios of the

190   quantifier and qualifier ions ($[M + Cl]^-$ two most intense isotopes) were compared to the obtained list

191   of *m/z*. When potentially interfering ions exhibited the same nominal mass, the theoretical resolution

192   necessary to discriminate was calculated and compared to the reached resolution of the Orbitrap at

193   the same mass (Table S3).

194

195 *2.5. Semi-quantification of CPs in vegetable oils*

196 An external calibration curve was built from the 4 technical mixtures used for method development as

197 well as the MCCPs mixture I-42. The dynamic range was 0.1-15 ng.μL^{-1} for each technical mixture. The

198 sum of the signal areas for each technical mixture normalised by the internal standard area was

199 expressed as a function of the mixture concentration. The procedural blank contribution was

200 subtracted from the samples before quantification.

201 In order to assess the similarity between the samples and each technical mixture, a least-squares

202 approximation with a non-negative constraint was calculated using the function *lsqnonneg* of the

203 *pracma* package in the *R* open source environment[23,33]. The profiles were considered as similar when

204 the parameter *a* of the equation $[S] = a \times [M] + b$ was equal to 1 (± 0.1), where $[S]$ and $[M]$ are the

205 vectors of the homologues detected in the sample and the corresponding technical mixture,

206 respectively.

207

208 **3. Results and discussion**

209 *3.1. Ionisation of CPs in ESI without modifier*

210 Analysis by LC-MS couplings being most commonly achieved with API sources such as ESI or APCI, the

211 ESI probe was first selected to investigate which type of ions would be created in this source. The

212 ionisation of the molecules depending on their chemical structure, and by extension, their chemical

213 properties, the impact of CP chain length and chlorine content on the ionisation was studied with four

214 standards: two SCCPs and two LCCPs standards, with low of high chlorine content. No additional

215 MCCPs standards was added in the mixture, as it was hypothesised that their behaviour would be

216 intermediate between SCCPs and LCCPs.

217 *The CP standard mixture* at 1 ng.μL^{-1} was thus injected in the LC-MS system with no modifier in the

218 mobile phase, according to parameters described above (§ 2.3). The temperatures of the capillary and

219 ESI probe were 300 °C and 150 °C, respectively, and the optical lenses tension was set to 50 AU. Three

220   ion types were monitored during the data treatment, according to CP ions previously reported in the

221   literature when using ESI: $[M - H]^-$ [25], $[M + Cl]^-$ [24], and $[M + C_2H_3O_2]^-$ [34]. Distinct profiles could be

222   observed, highlighting that the ions formation varies according to CP chemical formula (Figure 2,

223   Figure S1). SCCPs with low chlorine content were more prone to form $[M + C_2H_3O_2]^-$ ions whereas

224   SCCPs with high chlorine content were better ionised in the $[M + Cl]^-$ or $[M - H]^-$ forms. Regarding

225   LCCPs, the $[M + Cl]^-$ ions were formed predominantly, even if the $[M + C_2H_3O_2]^-$ ions were observed at

226   low intensity for LCCPs of low chlorine content. Interestingly, whereas $[M - H]^-$ ions were relatively

227   intense for SCCPs and would explain the choice of those ions when monitoring SCCPs[35], they weren't

228   formed for LCCPs.

229   The strong decrease of $[M + C_2H_3O_2]^-$ ions signal with increasing chlorine content as already reported

230   and explained by the difference of acidity between acetate and chloride[36], was confirmed in the

231   present study. Regarding the competition between $[M - H]^-$ and $[M + Cl]^-$ ions, it could also be related

232   to the acidity of the analytes that drives the affinity for one or the other ion formation. Indeed, $[M - H]^-$

233   are formed when molecules can lose a proton, which occurs mostly for acidic molecules (pKa < 5)[37].

234   Concerning CPs, as the hydrophilicity of the CPs decreases with increasing chain length, it can be

235   expected that the capability of CPs for losing a proton decreases accordingly, thus favouring

236      $[M + Cl]^-$ ions formation. Overall, the $[M + Cl]^-$ ions were formed regardless of the chlorine content or

237   the chain length of CPs homologues. As SCCPs and LCCPs could ionise in their $[M + Cl]^-$ form, it is

238   expected that an ionisation efficiency in between will also occur for MCCPs.

239   It is worth noting that $[M - HCl + Cl]^-$ and $[M - H]^-$ exhibit the same exact mass. Consequently, the

240   homologue pattern of the $[M - H]^-$ ions (Figure S1a) could partly come from interfering in-source

241   dechlorination products such as chlorinated alkenes, which can be formed by loss of HCl when CPs are

242   exposed to heat[38]. However, Schinkel et al.[38] showed that after 2 h at 220° C, only 22% hexachlorinated

243   tridecanes had degraded to hexachlorinated tridecenes. It can thus be hypothesised that CPs

244   degradation does not occur within the time spent in the ESI source, even though the probe

245   temperature of the experiment was higher. Moreover, as the intensity of the $[M - H]^-$ ions did not

10

246 increase with increasing probe temperature (Figure S4), we estimated that even if the observed

247 $[M - H]^-$ signal was interfered with CP degradation products $[M - HCl + Cl]^-$, this would have only a

248 limited impact on the overall distribution of the $[M - H]^-$, $[M + Cl]^-$, and $[M + C_2H_3O_2]^-$ ions in the source.

249 For a more robust conclusion, it would be necessary to study the degradation phenomenon with

250 constitutionally defined CPs[28]. Thus, the comparison of the intensities of the three adducts showed

251 that $[M + Cl]^-$ ions were the most suitable for all CPs analysis in a single injection, although the intensity

252 of the signal was a bit lower compared to acetate ions for SCCPs. Yet this choice prevents this method

253 from characterising the unsaturated homologues, as it cannot discriminate between chlorine adducts

254 of mono-unsaturated homologues and pseudo-molecular ions of saturated homologues. For CP

255 degradation studies, it would be preferable to use another target ion.

256

257 *3.2. Chlorine ions enhancement: influence of the modifier*

258 Although the four standards of the *CP standard mixture* were observed when monitoring the

259 $[M + Cl]^-$ ions, the signal was rather weak, especially for LCCPs, which can be explained by the lack of

260 sensitivity of ESI for hydrophobic compounds such as CPs[22]. It was already shown that signal

261 enhancement could be achieved in GC and LC analysis[22–24] for various instrumentations, mainly with

262 DCM addition, although chloroform[22] and more recently bromoform[26] were also reported, to form

263 $[M + Cl]^-$ and $[M + Br]^-$ ions, respectively.

264 Our selected mobile phase gradient involving a mixture of water and ACN, it was not possible to add

265 DCM directly into the mobile phases as it is not miscible with water. It could have been possible to add

266 the modifier only in the ACN, however DCM levels in the mobile phase would have consequently varied

267 during the elution, not to mention that its interaction with CPs shifts their elution (Figure S2). Hence,

268 we considered a previously reported post-column addition strategy[24].

269 Unfortunately, no significant trend in CPs signal areas was observed between DCM flow rates of 0, 0.02

270 and 0.04 mL.min^{-1}. We hypothesised that mixing pure DCM with the mobile phase was not favoured

271 under pressure conditions because of the presence of water. In order to favour the mixing, we replaced

11

272   pure DCM by a mixture of ACN/DCM (1:1, *v/v*) at a flow rate of 0.08 mL.min^{-1}. Great enhancement was

273   achieved between 0 and 0.08 mL.min^{-1}, with a signal increase from 91% for LCCPs highly chlorinated

274   to 616% for SCCPs lowly chlorinated (Figure 3). It is noteworthy that the LCCPs displayed the lower

275   signal increase, which is probably caused by their higher hydrophobicity. Nevertheless, addition of the

276   ACN/DCM mixture revealed all CPs compared to no addition.

277   In order to understand the mechanism associated to the observed signal enhancement, it would have

278   been interesting to investigate alternative halogenated modifiers (Table S4). However, although

279   chloroform, dibromomethane, bromoform, and diiodomethane were considered as potential

280   candidates with regard to their suitable melting and boiling points, the bromine and iodine chemicals

281   were not soluble with ACN and/or the mixture of ACN/H$_2$O. In our mobile phase conditions, only

282   chloroform was thus suitable. Hence, a comparison of the mixtures of ACN/DCM (1:1, *v/v*) and

283   ACN/chloroform (1:1, *v/v*) only was performed (Figure S3). No significant differences in homologue

284   summed intensities were observed, which was in good agreement with Zencak and Oehme findings[22].

285   Moreover, signals obtained with chloroform were less reproducible than signals obtained with DCM.

286   Since the chloroform was given a lower maximum professional exposure value than DCM by the French

287   National Institute for Research and Security (INRS, 2 ppm[39] and 50 ppm[40], respectively), DCM was

288   selected as modifier for the CPs analysis method.

289

290   *3.3. Optimisation of source parameters for chlorine ions monitoring*

291   Once the nature of the modifier was selected, the ionisation conditions were optimised to allow a

292   sensitive analysis of all CPs. Three main parameters of the HESI source were studied: the optical lenses,

293   the heater temperature and the capillary temperature (Figure S4, SI section 1). The highest signal

294   intensities were obtained for the highest temperature of the heater for all CPs, thus it was set at 350 °C.

295   For both the optical lenses and the capillary temperature, an opposite behaviour could be observed

296   between SCCPs low %Cl and LCCPs High %Cl. Consequently, different parameters could result in varying

297   relative responses between CP groups. This set of parameters should be considered whenever

12

298   comparing CPs intensity profiles between different methods. The optical lenses and capillary heater

299   were set at consensual values of 70 AU and 275 °C, respectively.

300

301   *3.4. Comparison of ESI and APCI*

302   ESI and APCI sources, involving different ionisation pathways, have been proven to be

303   complementary[41]. Comparison of their ionisation efficiencies can be of great interest. Schinkel and co-

304   workers have compared methods from the literature using either APCI or ESI. However too many

305   parameters were different between methods, which made it difficult to conclude. Thus, we compared

306   the response areas of $[M + Cl]^-$ adduct ions, using the parameters optimised in the present study for

307   ESI, and consensual parameters for APCI, selected from a similar experiment as for ESI (optical lens

308   voltage = 100 AU; probe temperature = 300 °C; capillary temperature = 200 °C) (Figure S6). ESI enabled

309   a higher signal response with relatively low standard deviations (<15%) for all CPs standards, and

310   particularly for SCCPs (5- to 7-fold) compared to APCI results. As the intensity of the SCCPs and LCCPs

311   were similar in APCI, it can be expected that the intensity of MCCPs would reach the same intensity

312   level. On the contrary, ESI ionised better SCCPs than LCCPs, thus it can be expected that MCCPs would

313   reach an intensity level in-between. Overall, higher sensitivity would be reached with ESI

314   independently of the chain length and was thus maintained as ionisation source for the analysis of CPs.

315   However, the parameters of APCI being different from those of ESI, it can be argued that comparison

316   of both instrumentations was limited. Notably, APCI usually demands higher mobile phase flow

317   (1 mL.min^{-1}), which could not be achieved due to back-pressure considerations. The ionisation

318   efficiency comparison should still be investigated for better understanding of CPs ionisation processes.

319

320   *3.5. Considerations on mass interferences*

321   Due to the highly complex isotopic profiles of CPs, concerns about interferences between homologues

322   have been previously reported[18,26,42]. For example, $[C_xH_{2x+2-y}Cl_y + Cl]^-$ ions differ of only 0.1591 Da from

323    $[C_{x+5}H_{2(x+5)+2-(y-2)}Cl_{y-2} + Cl]^-$ ions, which are not discriminated with low resolution instruments such as

324 quadrupoles and thus require chromatographic separation beforehand. Even though new mass

325 analysers were developed to reach high resolutions, the existence of various ions in the source makes

326 it even more complicated as stated by Yuan et al[18].

327 The high resolution of the Orbitrap system has already proven to discriminate SCCPs and MCCPs

328 homologue groups between them as well as from other halogenated contaminants, in GC-ENCI[5].

329 However, considering the decrease of the resolution when increasing the mass-to-charge ratio of the

330 target ion, a thorough analysis of the theoretical resolution of CPs with the Orbitrap available in our

331 laboratory was necessary, particularly for LCCP analysis. The *m/z* ratios of the quantifier and qualifiers

332 of the $[M + Cl]^-$ ions for each targeted CPs homologue were compared to the isotopologues of the

333 $[M - H]^-$, $[M + Cl]^-$ and $[M + C_2H_3O_2]^-$ ions. Notably, the resolution necessary to discriminate between a

334 diagnostic ion and its interfering ion was compared to the resolution of the Orbitrap (Table S3, cf. §

335 2.4). When no filter was applied, 181,347 potential interfering pairs (i.e a diagnostic ion and its

336 interfering ion) were found at nominal resolution, emphasizing the complexity of such mixtures.

337 However, numerous isotopologues are of very low theoretical abundance and would not significantly

338 interfere. With a threshold of 1% of theoretical abundance compared to the base peak for each isotopic

339 cluster, 45,641 interfering pairs were remaining. When a mass analyser exhibiting a resolution of

340 10 000 FWMH is used, this number decreases to 12,803. Applying the Orbitrap resolution filter, only

341 2,892 potential interfering pairs remained, which indicated that high resolution instruments are

342 decisive for LCCP analyses.

343 Among those 2,892 remaining interferences, 713 arose from the contribution of ^{13}C isotopologues in

344 the $[M + Cl]^-$ isotopic profile. This is thus not an external interference as it arises from the same

345 molecule and will always exhibit the same behaviour. The other 2,179 potential interfering pairs were

346 divided in 3 types of $[M - H]^-$ interferences and 2 types of $[M + C_2H_3O_2]^-$ interferences (Table S5). Three

347 types of interferences were occurring with ions with a theoretical abundance below 8% of the base

348 peak, which was considered as of low significance and will not be discussed in this paper. The fourth

349 interference occurs between the $[C_xCl_y + Cl]^-$ and $[C_xCl_{y+1} - H]^-$ ions with a mass difference of 0.0186 due

350   to the $^{35}Cl/^{37}Cl$ mass defect. However, the Orbitrap mass analyser was able to discriminate this mass

351   difference for a *m/z* up to 1000, thus only LCCPs ($C_{\geq 24}$) with very high chlorination degree ($\geq$ 17

352   chlorines) would be impacted. The fifth interference occurred between the $[C_xCl_y + Cl]^-$ and

353    $[C_{x-2}Cl_y + C_2H_3O_2]^-$ ions with a *m/z* difference of 0.0073 due to the $^{35}Cl/^{37}Cl$ mass defect and the ^{16}O

354   contribution. This smaller *m/z* difference was discriminated for SCCPs and lowly chlorinated MCCPs

355   but LCCPs would be strongly impacted. However, the formation of acetate ions is not favoured in the

356   chlorine-enhanced conditions of our method. We hypothesise that if some acetate ions are formed,

357   they will be in relatively low amounts compare to the chlorine ions.

358   Although the Orbitrap is highly performant, it does not overcome all the interferences potentially

359   occurring in such complex mixtures as LCCPs. Nevertheless, the remaining interferences can be

360   eliminated with optimised ionisation conditions as discussed above.

361   Besides interferences between CPs, potential interferences with other halogenated contaminants such

362   as toxaphenes, PCBs and other POPs were previously reported[42,43]. Thus, standards of

363   octachlorobornane, TBBPA, ^{13}C-HBCDD and a mixture of chlorinated POPs including lindane,

364   endosulfan sulfate, chlordecone and nonachlor were analysed in our optimized conditions and

365   potential interferences with CPs were investigated (Table S6). For almost all considered contaminants,

366   the necessary resolution was below 32,000, which is achieved by the used mass analyser

367   (R=140,000@200, meaning R=51,121@1500). However, two contaminants could require resolutions

368   >140,000. The first one is endosulfan sulfate, which forms an $[M - H]^-$ adduct that could interfere with

369   the C_8Cl_{10} CP homologue. The second one is HBCDD, which forms three major ions: $[M - H]^-$; $[M + Cl]^-$;

370   and $[2M + Cl]^-$. The two most intense isotopologues of the $[M - H]^-$ isotopic profile of ^{12}C-HBCDD could

371   interfere with the $C_{11}Cl_{13}$ CP homologue (R>200,000).

372   To separate these contaminants, chromatographic separation is necessary. In the developed method,

373   CPs are eluted from 2.5 ($C_{10}Cl_5$) to 14.5 minutes ($C_{34}Cl_4$). Broad homologues peaks (2-3 minutes large)

374   lead to the co-elution of SCCPs and MCCPs which then rely on the high resolution mass spectrometer

375   to be discriminated. However, a trend of elution according to the chain length and chlorine degree was

376   observed: SCCPs Low %Cl (2.5-4.5 min) < SCCPs High%Cl (4-6.5 min) < MCCPs (4.5-6 min) << LCCPs low

377   %Cl (7-14 min) = LCCPs High %Cl (7-10 min) (Figure S7). It is worthy to note that the peaks are enlarged

378   with longer chains, which can be explained by more positional isomers. Similarly, when the

379   homologues are highly chlorinated, the number of potential isomers decreases, leading to narrower

380   peaks (LCCPs high %Cl). With these chromatographic characteristics, the endosulfan sulfate was eluted

381   at 1.7-2.2 minutes which is earlier than any CP. Similarly, the retention time window of the $C_{11}Cl_{13}$ CP

382   was [5.2-6.6] min whereas the retention times of α-, β- and γ-HBCDD were [3.3-3.6], [3.6-4.0] and [4.3-

383   4.8] min, respectively (Figure S8). Thus, in both cases, the liquid chromatography enabled the

384   separation of contaminants that would interfere with CPs. The combination of both high resolution

385   and chromatographic separation improved the selectivity of the method.

386

387   *3.6. Application of the optimised method to vegetable oils from French market*

388   The optimised method was applied to olive, hazelnut, and linen oils from French markets. Olive and

389   hazelnut oils exhibited profiles dominated by MCCPs, although hazelnut oil profile contained SCCPs

390   and LCCPs as well (Figure 4a and 4b). This is in accordance with recent studies showing a shift from

391   SCCPs to MCCPs occurrence in environmental samples[38,39]. Linen oil featured a more complex profile,

392   from SCCPs lowly chlorinated to LCCPs highly chlorinated. Interestingly, homologue groups presenting

393   more chlorine than carbon atoms were detected for C_{13} and C_{14} chain lengths, although they were not

394   expected according to the already described synthesis mechanism as mentioned earlier. These

395   homologues could be the result of synthesis performed in extreme conditions (high temperature, very

396   long reaction time, high concentration of chlorine).

397   Finally, a profile similar to the CPW-100 standard (Dr. Ehrenstorfer) was observed in linen oil (Figure 1,

398   Figure 4c), at a level similar to MCCPs (81 ng.g^{-1} lw). This profile is particularly highly chlorinated, the

399   most intense homologues containing as many chlorines as carbons. LCCPs have already been detected

400   in sewage sludge[20,34], fish and seafood[23], and human blood[24]. However, to our knowledge, it is the first

401 time that such a highly chlorinated profile is reported in food samples, which may result from the

402 optimisation of the method that was dedicated towards longer and higher chlorinated CPs.

403 A semi-quantification CPs was attempted using the technical mixtures used for method development

404 as well as I-42. The MCCP technical mixture (I-42), SCCPs high %Cl and LCCPs high %Cl were very similar

405 to the profiles observed in the samples (Table S7), which allowed quantifying this type of CPs. The

406 traces of SCCPs low %Cl found in the oils most likely came from a MCCP technical mixture with SCCP

407 impurities, hence could not be totally matched to the quantification mixture. Nevertheless, MCCPs

408 were estimated at 76-267 ng.g^{-1} lw (Table S8), which was several times higher than SCCPs that were

409 neither detected or quantified below 79 ng.g^{-1} lw. SCCPs were investigated in vegetable oils from China

410 and were found to vary from a few to thousands of ng.g^{-1} [44]. In our work, we showed that SCCPs

411 represent only part of the CP contamination. Most importantly, LCCPs high %Cl were estimated at 81

412 ng.g^{-1} lw, which is in the same range than SCCPs and MCCPs. Although it has been mentioned that the

413 toxicity of CPs may decrease with increasing chain length[45], it was also shown that highly chlorinated

414 CP technical mixtures (70% Cl) had neurobehavioral effects on zebrafish[45]. The toxicity of LCCPs is still

415 controversial and should not be underestimated, as stated by the European Food Safety Authority

416 recently[47] Thus, it enhances the need for as much comprehensive analytical methods as possible for

417 the sake of CPs human exposure assessment.

418

419 **4. Conclusions and perspectives**

420 To date, there is still no consensus on CPs analysis due to their complex composition and associated

421 physicochemical properties. Analytical methods reported until now face interferences, poor or varying

422 ionisation depending on homologue/isomer pattern. In order to achieve efficient analysis of such

423 compounds and harmonize the approaches, it is crucial to widen and share the knowledge related to

424 all the factors which come into play, from instrumentations to quantification procedures[48]. Our work

425 focused on a critical step of their analysis related to ionisation prior to MS monitoring, thus

426 complementing the recent study of Zheng et al.[49] which discussed the dependence of the ionisation

427 efficiency on the selected modifier and monitored adducts for CPs up to C_{20}. In the present study, we

428 considered a more global range of CPs from C_{10} to C_{36} and from Cl_4 to Cl_{30} for the longest chains, thus

429 highlighting the opposite behaviours between SCCPs and LCCPs and the limitation of intensity profiles

430 comparison.

431 Overall, the chlorine-enhanced RPLC-ESI-Orbitrap method optimised in the present study enables the

432 identification of SCCPs, MCCPs and LCCPs in one single injection, at relatively comparable response

433 although SCCPs are slightly favoured. The in-house software enables the semi-automatic integration

434 of 573 homologue groups (C_8-C_{36}, Cl_4-Cl_{30}) in a few minutes. Moreover, we demonstrated that the

435 resolution of the Orbitrap mass analyser allows for the discrimination of all homologue groups without

436 significant interference contribution when appropriate ionisation conditions are used, but should be

437 used after chromatographic separation of halogenated contaminants from CPs.

438 The optimised method was applied to commercial vegetable oils (n=3), which were found to be

439 contaminated with SCCPs, MCCPs and LCCPs with a majority of MCCPs. Most importantly, linen oil was

440 found to be contaminated with as much highly chlorinated LCCPs as MCCPs and SCCPs. This emphasises

441 that more attention should be paid to unusual CPs. It is thus crucial to pursue effort on comprehensive

442 studies to expand the CP dietary exposure assessment.
