1 **ABSTRACT**

2 The puppy, born without immunoglobulins G (IgG), acquires a passive systemic immunity
3 thanks to colostrum intake during the two first days of life. The quality of passive immune
4 transfer (i.e. blood IgG concentration at two days of age), highly variable between litters and
5 between puppies within litters, depends mainly on the time elapsed between birth and
6 ingestion of colostrum, with limited influence of colostrum IgG concentration. Deficit in
7 passive immune transfer, impacting puppy's health and neonatal mortality rate, can be
8 indirectly diagnosed through blood gammaglutamyltransferases assay and evaluation of growth
9 rate over the two first days of life. In the absence of maternal colostrum, few homo and
10 heterospecific immune sources are available and canine colostrum banking remains the optimal
11 solution. Whereas passive immune transfer is crucial for survival during the neonatal period,
12 it later interferes with response to vaccination. In addition to systemic passive immune
13 transfer, maternal antibodies (mainly IgA) would provide local (digestive) immunity, ensuring
14 mid-term protection of the puppies' gut together with probably long term training of the
15 digestive immune system.

1 **I. Introduction**

2 Neonatal period in the canine species, defined as the first three weeks of life, is a critical period
3 with high risk of mortality: about 10% of all live-born puppies die between birth and 21 days
4 of age (Mugnier et al. 2018). Survival rate during this period depends on the ability of the
5 newborn to adapt to the extra uterine life. Once cardiorespiratory system has been able to
6 switch from a placental to an aerial oxygen provision, the newborn dog goes through new
7 challenges, both immune and nutritional. From the nutritional point of view, the circulation of
8 nutrients via placenta is interrupted at birth; nutrients supply relies on implementation of new
9 strategies by the newborn, including mammary gland approach, suckling and milk digestion.
10 The immune situation of the newborn dog is critical, as the endotheliochorial structure of the
11 placenta drastically limits transplacental transfer of macromolecules, including immunoglobulin
12 G (IgG), to the newborn's bloodstream. Whereas exposed to high concentrations of infectious
13 agents immediately after birth when delivered out of the uterus, puppies are born with very
14 low systemic immunity, with mean serum IgG concentration at about 0.3g/L versus 8-25g/L in
15 the adult dog (Poffenbarger et al. 1991; Bouchard et al. 1992; Chastant-Maillard et al. 2012;
16 Mila et al. 2014a). Transfer of passive immunity from dam to the offspring is thus essentially
17 lactogenic in the canine species, colostrum ensuring both nutrients and immunity provision: at
18 two days of age, mean serum IgG concentration in the puppy rises up to 6-16 g/L, with 85-
19 95% of the immunoglobulins originating from the colostrum transfer (Pollock and Carmichael,
20 1982; Poffenbarger et al. 1991; Schäfer-Somi et al. 2005a; Greene and Schultz, 2006; Day, 2007;
21 Chastant-Maillard et al. 2012; Figure 1). Even when evaluated to its maximum (two days of
22 age), immunoglobulins concentrations or specific antibody titers acquired by the puppy after
23 colostrum intake remain lower than in the adult dog, reaching (between 50 and 77% of the
24 maternal level (Mila et al. 2014a; Gillespie et al. 1958).

1 Unlike in the piglet or calf, the passive immune transfer (PIT) was investigated in the dog only
2 recently. The aim of this review is to present different factors influencing quality of the PIT
3 (defined as the serum IgG concentration acquired at two days of age), to describe the impact
4 of PIT on puppies' health, and to comment on the alternatives to colostrum. Physiology of PIT
5 in the dog and the methods of its evaluation will be also addressed.

6 **2. Definition of passive immune transfer in the dog**

7 Adequate PIT is essential for the puppy as its low quality is associated with an increased risk
8 of neonatal mortality: mortality between birth and three weeks of life in puppies with serum
9 IgG concentration at or below 2.3g/L was 44.4% versus 4.9% in puppies with higher IgG
10 concentration ($p=0.001$; Mila et al. 2014a) ; mean blood IgG concentration at Day2 of life was
11 2.32 g/L in puppies dying between Day 2 and 21 vs 6.94 g/L for puppies still alive at 21 days of
12 age). The minimal protective level of IgG concentrations are very different depending on
13 species: 4-8g/L in the foal, 10g/L in the calf and 15g/L in the piglet (Weaver et al. 2000; Cabrera
14 et al. 2014; Liepman et al. 2015).

15 In order to determine a real prevalence of the deficit in PIT, data on large number of puppies
16 from different kennel conditions still remain to be obtained. This deficit was diagnosed in one
17 out of 20 puppies (5%) according to Gooding and Robinson (1982) and in 26 out of 149 puppies
18 (17.4%) according to Mila et al. (2014a). Indeed, the prevalence of the deficit in PIT varies
19 strongly among kennels, but may vary also among breeds, as only 4 out of 90 Labrador puppies
20 (4.4%) presented IgG concentration below 2.3 g/L (unpublished data). In case of free suckling
21 (uncontrolled by the breeder), quality of PIT is strongly variable among litters, but also among
22 puppies from the same litter, both evaluated via serum IgG concentration (general immunity)
23 and via CPV2-specific antibody titer (specific immunity; Figure 2) (Mila et al. 2014b).

24 **3. Evaluation of passive immune transfer**

1 Although IgG is not the only molecule with immune activity provided to the newborn via
2 colostrum intake (see below), its absorption witnesses colostrum intake, making serum IgG
3 concentration assay at 2 days of age the reference method for PIT evaluation (Poffenbarger et
4 al, 1991; Chastant-Maillard et al 2010; Mila et al, 2014). IgG assay performed via an immuno-
5 enzymatic method (ELISA - Enzyme-Linked ImmunoSorbent Assay) is not an automated
6 process and requires about six hours of laboratory work, limiting its use to scientific purposes.
7 In practice, PIT can be evaluated indirectly through blood gamma-glutamyltransferases (GGT)
8 activity at two days of age: GGT activity in canine colostrum is ten times higher than that in
9 the female blood, whereas GGT activity in puppies' serum at birth is almost absent. Any
10 increase of GGT activity in the newborn's serum is indicative of an ingestion of colostrum
11 (Center et al. 1991), with an activity below 62U/L diagnosing a deficit in PIT with a 87.5%
12 sensitivity and a 80% specificity (Mila et al. 2017b). PIT can be also evaluated via specific
13 antibody titer. Indeed, at two days of age, serum IgG concentration and CPV2 specific-antibody
14 titer are positively correlated, with concordant diagnosis of adequate PIT in 88% of puppies;
15 adequate PIT was defined as IgG concentration > 2.3g/L for general immunity and CPV2-
16 antibody titer > 1:80 for specific immunity evaluation (Mila et al. 2018).

17 Easy-to-use, but also non-invasive, tests of the evaluation of the quality of PIT remain still to
18 be developed for the canine species. Namely, all above mentioned methods require blood
19 sampling of the newborn, in Newfoundland puppy of mean birth weight of 630g, as well as in
20 a 120g Chihuahua (A. Mugnier, personal communication). Knowing that dog breeders are
21 forbidden to draw blood samples in most countries, and taking into account the cost of
22 veterinary consultation (ideally at the kennel, since speaking of two-day-old puppies) and the
23 cost of the blood test itself, such blood screening cannot be implemented in practice. An easier
24 and costless method of indirect PIT evaluation is early growth monitoring, i.e. the percentage
25 of weight gain from birth to two days of age, since colostrum provides together energy and

1 immunoglobulins. A growth rate over the first two days of life below -2.7% allowed to identify
2 the deficit of PIT in 87-96% of cases, both in terms of general (IgG) and specific (CPV2-specific
3 antibodies) immune transfer (Table I; Mila et al. 2018).

4 **4. Factors determining the quality of passive immune transfer**

5 In any species, final blood IgG concentration at two days of age depends on the quantity of
6 IgG ingested by the newborn and on the proportion of IgG absorbed from the newborn gut
7 into its bloodstream. Three factors thus influence the quality of PIT: i) the immunological
8 quality of the colostrum (evaluated via IgG concentration), ii) the volume of colostrum ingested
9 by the newborn, and iii) the time elapsed between birth and colostrum ingestion.

10 *4.1. Immunological quality of the colostrum*

11 *4.1.1 Colostrogenesis*

12 Immunoglobulin concentrations in canine mammary secretions are elevated during the first
13 two days post-partum compared with later in lactation, defining this period as the colostrum
14 phase in the canine species. Three immunoglobulin classes are present in the canine colostrum
15 (IgA, IgM and IgG), IgE remaining at undetectable concentrations (Chastant-Maillard et al.
16 2010).

17 IgA represent between 16 and 40% of total colostrum immunoglobulins at the onset of lactation,
18 becoming the principal immunoglobulin class in the mature milk (Schafer-Somi et al. 2005b;
19 Chastant-Maillard et al. 2010). As IgM, IgA are mainly produced locally by the lymphocytes of
20 the mammary tissue (Hurley and Theil, 2011). Once ingested into the gut, IgA participate
21 locally in the immune defense mechanisms of the digestive epithelium. Apart from this local
22 role, a part of IgA passes through the intestinal wall, being absorbed into the bloodstream and
23 subsequently redistributed onto the mucous surfaces, digestive or not (Salmon et al. 2009;
24 Chastant-Maillard et al. 2012); they thereby participate for example in the immune defense of
25 the respiratory tract. IgA concentration in the colostrum is between five and ten times higher

1 than in adult serum, whereas that of IgM is much lower than in the serum, only about 15-25%
2 of the serum concentration (Day, 2007; NeoCare unpublished data).
3 IgG, main actor of the systemic immunity, is the major immunoglobulin class of the colostrum
4 (60-75% of total immunoglobulins). Only a very small proportion of colostrum IgG are produced
5 by the mammary tissue, with the vast majority originating from the maternal blood. At the end
6 of gestation, blood IgG circulating in the maternal bloodstream are trapped into the mammary
7 tissue and stored until lactation onset. The involvement of the FcγR_n receptors (Fragment,
8 crystallizable receptor, neonatal) in the IgG mammary storage remains unclear and has never
9 been studied in the canine species (Cervenak and Kacs Kovics, 2009). The drop in blood
10 progesterone concentration at parturition induces the increase of prolactin secretion and the
11 onset of the lactation: IgG are then released into the mammary alveoli lumen and excreted
12 into the colostrum (Hurley and Theil, 2011). Mean IgG concentration in the canine colostrum
13 is of about 20 g/L (Schafer-Somi et al. 2005a; Chastant-Maillard et al. 2010; Mila et al. 2015a),
14 i.e. 2-3 times higher than in the maternal serum (between 0.9 and 6.3 times depending on the
15 dam).

16 *4.1.2 Variation factors of the colostrum quality*

17 Immunological quality of the colostrum is amazingly variable between bitches: mean
18 concentration of colostrum calculated as the mean of concentrations obtained separately from
19 the five pairs of mammary glands of an individual varies from 3 to 69 g/L, without any influence
20 of the breed or litter size (Mila et al. 2015a). Age may have an impact, with colostrum of better
21 immunological quality in females below six years of age than in older bitches.

22 In addition to this huge inter-individual difference, colostrum IgG concentration also varies for
23 one given bitch among the different pairs of mammary glands, with a mean intra-individual
24 coefficient of variation of $42 \pm 32\%$. For one given bitch, the highest and the lowest IgG
25 concentrations as assayed by mammary pairs differ in average by a factor of 5.9 (Chastant-

1 Maillard et al. 2017). However, when numbered (M1 anterior thoracic to M5 posterior
2 inguinal), none of the five pairs of mammary glands secreted systematically colostrum of better
3 (or worse) immunological quality. No practical recommendation can be thus drawn for dog
4 breeders to encourage suckling of a specific pair of mammary gland to optimize PIT. In the
5 cow, posterior quarters produce colostrum of higher IgG concentration (Gross et al. 2016),
6 whereas in the sow, reported results are controversial (Klobasa and Butler, 1987; Wu et al.
7 2010). Such a difference in colostral IgG concentration could be due to differences in
8 vascularization between the different pairs, or to different densities in FcγR_n receptors.

9 The eventual impact of such a variability in colostrum quality between teats on the quality of
10 PIT depends on the suckling behavior of the puppy, and more precisely on the choice of the
11 teat. Unlike piglets or kittens, puppies' siblings do not develop any competitive behavior for
12 teat appropriation. In average, a puppy suckles 5 ± 2 teats over the first 12h of life (before the
13 intestinal barrier closure), with M5 (posterior inguinal) being the most often suckled (Figure
14 3). Such multiple teat shifts contribute to erase the impact of the difference in colostral
15 immune quality per teat. Later, data obtained during the second and third day of lactation
16 showed that puppy suckles an average of 2.5 ± 0.8 teats per feeding session (Arteaga et al.
17 2013).

18 To date, no method is available for IgG concentration evaluation in canine colostrum in kennel
19 conditions. Refractometry, routinely used in the cow and mare, is not a reliable method of
20 colostrum quality evaluation in the bitch (Mila et al. 2015a). As no correlation between
21 colostral and serum IgG concentrations was evidenced in the bitch (Chastant-Maillard et al.
22 2010; Mila et al. 2015a), prediction of the colostrum quality according to maternal blood IgG
23 level is neither possible. Evaluation of the repeatability of colostrum quality along with
24 lactations of one given bitch would be desirable for breeding selection purposes, but also to
25 decide which neonates would require the administration of a colostrum replacer.

1 Nevertheless, no correlation has been demonstrated between mean colostrum IgG
2 concentration (mean value from 5 pairs of mammary glands per bitch) and serum IgG
3 concentration in the newborn at two days of age in a study on 139 bitches and their 651
4 puppies from various breeds (Aggouni, 2016). No effect on the incidence of deficit of PIT (see
5 below) was either evidenced. According to a theoretical approach presented in Figure 4, a
6 puppy receiving an adequate volume of colostrum at an adequate time (see below) would meet
7 the passive immune transfer requirements (serum IgG at or below 2.3g/L) only if provided
8 with colostrum with more than 3.4 g/L of IgG. As only one out of the 139 tested bitches had
9 colostrum below this threshold, colostrum immunological quality does not seem to be a
10 frequent limiting factor for PIT in the canine species.

11 *4.2. Quantity of colostrum ingested*

12 Gastric capacity in the newborn dog is estimated at four ml per 100 g of body weight, with a
13 mean gastric emptying time of two hours. However, the actual mean volume of colostrum
14 ingested by the newborn dog remains unknown to date. Based on calculation presented in
15 Figure 4, the quantity of a colostrum of medium quality (IgG concentration of 20g/L) necessary
16 to achieve the minimum blood IgG level (2.3 g/L) is 1.3ml for each 100g of newborn body
17 weight.

18 *4.3. Time elapsed between birth and colostrum ingestion*

19 The delay elapsed from birth decreases both the colostrum immune quality and the intestinal
20 potential to absorb immunoglobulins. On the maternal side, colostrum IgG concentration
21 drops dramatically after whelping with a mean decrease of 60% ($\pm 18\%$) between 4 and 24h
22 post-partum (Albaret et al. 2016). For the neonate's part, intestinal barrier closure is one of
23 the main factors determining the quality of PIT. Histological description of this phenomenon,
24 non available in the dog, is known in the bovine and porcine species. At birth, tight junctions
25 between enterocytes as well as brush border of these cells are undeveloped. Macromolecules,

1 including immunoglobulins, can pass through digestive mucosa and be absorbed into the lymph
2 and later into the bloodstream. This transport seems to be non specific and most probably
3 independent from FcγR_n receptors (Cervenak and Kacs Kovics, 2009). Bioavailability of colostrals
4 immunoglobulins is highly due to a weak proteolytic activity of the digestive system at birth,
5 immature digestive microbiota but also thanks to a high concentration of trypsin inhibitors in
6 the ingested colostrum (1000 times higher than in the mature milk-in the cow) (Levieux and
7 Ollier, 1999). As early as birth, over the first hours of life intestinal permeability decreases:
8 puppies at birth absorb in average 40% of ingested IgG, whereas absorption rate drops at 20%
9 4h later, and at only 9% 12h later. After the first 12-16 hours of life, IgG absorption rate is
10 absent (Chastant-Maillard et al. 2012).

11 Thus, in order to optimize PIT, the colostrum intake must take place as early as possible, and
12 in any case during the first 8 hours of life. Spontaneous suckling behavior in early life is largely
13 unknown in the canine species. Recently, we observed during the first 24h of life five Labrador
14 litters with free suckling. In the 35 included puppies, the first suckling was observed between
15 five minutes and six hours after birth, with 70% of puppies suckling for the first time during
16 the first two hours. Over the first 12 hours of life, each puppy suckled during in average 80 ±
17 40 minutes (11% of the total duration of life) in 10 sessions (Viaud, 2018). Suckling behavior
18 seems to naturally promote an adequate PIT.

19 **5. Long-term consequences of passive immune transfer**

20 *5.1. Systemic passive immune transfer*

21 After intestinal barrier closure in the newborn, serum IgG concentration drops exponentially,
22 with an IgG half-life from 8.4 to 13.4 days. Depending on their specificity, maternally derived
23 antibodies (MDA) persist until 10-15 days of life (Gooding and Robinson 1982; Pollock and
24 Carmichael 1982; Greene and Schultz 2006; Mila et al. 2014b). In the dog, the MDA
25 concentration falls at 1 to 3% of the initial level as early as 30 days after birth (Chappuis, 1998).

1 However, this drop of circulating MDA tends to be accelerated in presence of pathogens in
2 the environment or due to repeated vaccinations, by consumption within the immune
3 response. Immune complexes formed are then secreted into the intestinal lumen through
4 FcγRn receptors (Rath et al. 2003; Greene and Schultz, 2006). The postnatal drop in MDA
5 seems breed-dependent, with shorter half-time in rapidly growing puppies (Chappuis, 1998).
6 In parallel to the decrease in MDA, the newborn dog is able to produce its own antibodies
7 since birth, with a significant increase of antibody concentration visible as early as 14-21 days
8 of age (Figure 1).

9 The quality of PIT at two days of age correlates with the specific immunity level and thus with
10 health status of the neonate. In a kennel with spontaneous CPV2 circulation, puppies with
11 CPV2-specific antibody titer above 1:160 at two days of age were longer protected against
12 parvovirus infection and excreted CPV2 significantly later in the pre-weaning period than
13 puppies with lower MDA levels (45 vs 38 days of age, respectively; Figure 5). Mortality rates
14 between 2 and 56 days of life were also significantly different in the two groups: 7% (3/45) and
15 26% (9/34), respectively (Mila et al. 2014b). The survival rate over the entire neonatal period
16 is thus markedly influenced by the quality of specific PIT, with MDA probably preventing the
17 infection thanks to virus neutralization (Mila et al. 2014ab).

18 Although puppies with an adequate PIT may not exhibit any clinical signs of infection, they may
19 still actively participate in the virus circulation by shedding virus (Elia et al. 2005). They may
20 put at risk some vulnerable puppies (i.e. with failure of PIT), if introduced into a kennel naïve
21 to CPV2. Indeed, MDA persistence at the time of vaccination at about 8 weeks of age is
22 problematic to dog breeders. Although puppies are able to produce antibodies in response to
23 natural infection or vaccination since birth (and even during the fetal life), seroconversion
24 occurs only in the absence of specific MDA (Gooding and Robinson, 1982; Chappuis, 1998;
25 Toman et al. 2002; Day, 2007). A so called *immunological gap* appears, with remaining MDA

1 preventing the mount of a correct response to vaccination whereas no more providing puppy
2 with adequate immune protection (Decaro et al. 2005). Among 88 puppies vaccinated against
3 CPV2 between 8 and 10 weeks of age, eight puppies did not develop a protective response
4 due to the presence of MDA (Thibault et al. 2016). Taking into account the late presence of
5 colostral MDA, a third vaccination at about 16 weeks of age was implemented in 2015 into
6 the international recommended vaccination protocol (WSAVA 2015; Day 2017).

7 *5.2. Local passive immune transfer*

8 Beside the transfer of MDA, colostrum also ensures the acquisition of other immune
9 compounds, suspected in puppies based on information obtained in large animals. Colostrum
10 and later, milk- contributes to local digestive immunity by IgA, participating into the
11 enteropathogens neutralization within the intestinal lumen. Except IgA, other nonspecific
12 colostral compounds, such as lysozyme and lactoferrin, participate in the newborn immune
13 response, even though they are considered of minor importance (Handl et al. 2009). In other
14 domestic animals, white blood cells, such as macrophages, neutrophils and lymphocytes are
15 other compounds of the PIT: these cells are able to cross the intestinal barrier and enhance
16 neonatal immunity during the first month of life (Liebler-Tenorio et al 2002; Langel et al, 2015,
17 2016). They release IgA locally when in contact with digestive pathogens (Wheeler et al. 2007).
18 Globally, colostrum increases the digestive immunity thanks to the presence of non-specific
19 antimicrobial factors, controls the development of the digestive microbiota, modulate
20 development of Peyer's patches and digestive epithelium, participate in the adequate immune
21 response. Stimulation of the intestinal immune system (the most developed one of the entire
22 organism) during the first days of life is essential to adapt the immune response and to limit
23 infections, inflammatory diseases and allergies (Kelly et al. 2000; Rogier et al. 2014). Facing the
24 marked unexplained increase in the prevalence of dysimmune diseases and inflammatory
25 processes (including obesity) in the dog (Sundlund et al. 2016; Banfield, 2018), the impact of

1 systemic, but also digestive immunity established during the first days of life on the long-term
2 health remains to be investigated.

3 **6. Alternatives to colostrum for passive immune transfer**

4 In some situations, colostrum is not available to puppies, or in limited quantities. In the absence
5 of the dam, absence of maternal behavior, insufficient colostrum production according to the
6 litter size and puppy's inability to suckle, an alternative to maternal colostrum should be
7 administrated. An optimal colostrum replacer should provide puppies with an adequate energy
8 but also immune supply, the last one making this nutritional solution a challenge for veterinary
9 industries. Numerous colostrum replacers are available, homo or heterologous, designed from
10 mammary secretions, blood products or egg products. Only a few of them were scientifically
11 evaluated regarding puppies' PIT and/or health. Besides the effect on the systemic PIT,
12 evaluation of the local digestive immune action, as well as its short and long term consequences
13 on the health status of the supplemented animal would be of interest. Whatever the type of
14 colostrum replacer, it should be administrated, similarly as maternal colostrum, during the first
15 eight hours of life, via a baby bottle or feeding tube. Although bottle feeding is a procedure
16 closer to the physiological suckling, feeding tube allows to control the volume and the time of
17 colostrum ingestion. Dog breeders, often reluctant to tube feeding, should be encouraged to
18 learn this technique, in order to deal with urgent situations and be able to increase chances of
19 appropriate PIT.

20 *6.1. Colostrum/milk*

21 *6.1.1. Canine colostrum*

22 Frozen canine colostrum is to date the best alternative to maternal colostrum, as practiced in
23 bovine and equine species. The optimal time for colostrum collection from the donor bitch is
24 a compromise between the physiological drop in colostrum immune quality after parturition
25 (50% of the initial IgG concentration as early as 24h post-partum) and the time required for

1 the donor's own litter to acquire PIT (intestinal barrier closure at 12-16h of life). The donor
2 bitch can thus be milked during its second day of lactation. Preferably, the colostrum should
3 be obtained from bitches housed in the same kennel, recently boosted with vaccines before
4 whelping, and whose previous litters exhibited low mortality rates and high growth rate over
5 the first two months of age.

6 Manual milking of a bitch is rather easy to proceed, but oxytocin injection may be helpful in
7 some females (1-2 UI SC a couple of minutes before milk collection). After teats are cleaned
8 and dried, colostrum is collected into 1-5ml plastic tubes to be immediately stored at -20°C.
9 Attention must be taken concerning the hygiene conditions at the collection, as the collected
10 secretions are intended to be later administered to highly vulnerable individuals. In human
11 medicine, the recommended maximum duration for frozen colostrum storage is 6 months;
12 one year in bovine and equine neonatology. Thawing using microwave oven is has to be
13 avoided, as this process destroys immune potential of antibodies. It is rather recommended
14 to thaw colostrum at 37°C, preferably using baby-bottle warmer or water-bath. After thawing,
15 colostrum is administrated to the newborn dog at the dose of 1.5ml per 100g of body weight.
16 To date, colostrum banking is the best solution aiming to replace the maternal colostrum,
17 providing the newborn with energy and immunity, but also with hormones and growth factors,
18 even though white blood cells are destroyed.

19 *6.1.2 Canine mammary secretions after the colostral phase*

20 Mean IgG concentration in canine mature milk is 1-2g/L, compared with 20g/L in the
21 colostrum, and far below the minimal threshold avoiding failure of PIT in puppies. No data are
22 available in puppies, but no significant increase in serum IgG concentration has been evidenced
23 in kittens treated with mature milk of a donor queen (Claus et al. 2006).

24 *6.1.3. Canine mammary secretion of pseudopregnancy*

1 IgG concentration in pseudopregnancy secretions ($11.6 \pm 9.9\text{g/L}$) was not significantly different
2 from those measured in the colostrum ($18.0 \pm 12.0\text{ g/L}$), but significantly higher than in the
3 mature milk ($2.0 \pm 1.3\text{ g/L}$). Similarly, as for the colostrum, IgG concentration may vary by a
4 factor of 1.6 to 8.8 for one given bitch (Abrard et al, 2018). Immune transfer obtained in
5 puppies after ingestion of pseudopregnancy secretions is to be evaluated to validate their
6 interest as colostrum substitutes.

7 *6.1.4. Bovine colostrum*

8 Bovine colostrum is an alternative source of antibodies, easily available in large quantities.
9 However, its immune interest for the canine newborn, never evaluated, would be probably
10 limited, as bovine colostrum is free from antibodies directed against major canine pathogens,
11 such as antibodies targeting CPV2.

12 *6.1.5. Milk replacers*

13 No canine immunoglobulins are present in industrial milks, modified from bovine milk. No PIT
14 can thus be expected from these formulas.

15 *6.2. Canine serum or plasma*

16 Despite containing antibodies directed against canine pathogens, canine blood products display
17 IgG concentration at about three times lower of that of the canine colostrum. In case of oral
18 administration of canine serum to colostrum-deprived newborn puppies, the increase in their
19 blood IgG concentration was insignificant compared with that achieved after ingestion of
20 maternal colostrum and below the threshold defining failure in PIT (Poffenbarger et al. 1991;
21 Bouchard et al. 1992; IgG threshold at 2.3 g/L from Mila et al 2014a). Oral administration of
22 the canine plasma during the first eight hours after birth to puppies with free access to the
23 dam and the colostrum, did not allow to reduce the proportion of puppies at deficit of PIT
24 (Mila et al, 2014a), but a tendency for a lower morbidity rate in supplemented puppies was
25 observed (Mila et al. 2017a). Only parenteral administration, with associated risks, was

1 suggested to allow PIT: a subcutaneous injection of 2ml or 4mL/100g body weight at birth
2 allowed to reach mean IgG concentrations of respectively 2.6 and 4.5 g/l (Bouchard et al.
3 1992). However, some severe lesions have been reported after such a treatment: “impressive
4 subcutaneous pockets of liquid” according to Bouchard et al. (1992) until large (> 10cm) skin
5 necrotic zones in our own experience.

6 No study was conducted in puppies with administration of heterospecific serum for PIT
7 acquisition. In kittens, equine serum and purified equine antibodies given orally transferred no
8 significant passive immunity (Crawford et al. 2003). Besides the effects on systemic immunity,
9 early supplementation (before the intestinal barrier closure) with canine plasma was associated
10 to an increased diversity of microbial digestive communities, whose long term consequences
11 remain to be explored (Mila et al. 2017a).

12 6.3. Hyperimmune egg powder

13 Hens vaccinated against canine antigens produce antibodies targeting those antigens. These
14 antibodies (called IgY, for yolk immunoglobulins) are secreted in the egg yolk at high
15 concentrations and can thus be easily available, in large amounts and in a non invasive way.
16 Benefits of CPV2-specific and *E. coli*-specific IgY on the canine neonate have been recently
17 demonstrated, as large breed puppies receiving IgY orally once before the intestinal barrier
18 closure presented greater growth rate over the neonatal period (D0-D21) than controls:
19 824±349g in IgY supplemented puppies vs 662±334g in controls, n=334 puppies (Mila et al.
20 2017a). Such colostrum alternative containing CPV2-specific and *E. coli*-specific IgY is available
21 for dog breeders (PuppyProTech, Royal Canin, Aimargues, France). IgY supplementation is a
22 strategy validated in other species (Diraviyam et al 2014) and promising for the canine
23 newborns since IgY directed against numerous canine pathogenic bacteria (as for example
24 *Salmonella*), viruses (canine coronavirus CCoV, canine herpesvirus CHV1 ...) and parasites
25 (*Giardia*) could be produced. IgY half-life in the puppy’s bloodstream is unknown to date, but

1 probably short, as the half-life of IgY administered to piglets at 10 hours of life was of 1.85h
2 versus 12 days for homologous IgG (Yokoyama et al. 2003). Nevertheless, the effect of IgY
3 administration in the newborn probably relies not only on passive immune transfer, and its
4 role on the digestive microbiota and digestive immune competences are to be explored.

5 **7. Conclusions**

6 Systemic passive immune transfer in puppies depends mainly on the time elapsed between
7 birth and colostrum ingestion rather than on the immune quality of colostrum. While PIT is
8 recognized as essential for neonatal health in other species, such as bovine, equine and porcine,
9 it is often neglected in the canine. Scientific knowledge in this area is to be transferred to
10 breeders, encouraging colostrum banking and early colostrum ingestion. Controlled suckling
11 in canine newborns could contribute to decrease neonatal mortality rate, improving financial
12 situation in kennels and animal welfare.

13 **Funding**

14 Authors research on passive immune transfer in puppies was partially supported by Merial
15 (Lyon, France) and Royal Canin R&D (Aimargues, France).

16 **Acknowledgments**

17 Authors want to thank all breeders and all veterinary students who participated in
18 improvement of knowledge about passive immune transfer in the dog, and particularly
19 Charlotte Aggouni, Amélie Albaret, Morgane Delebarre, Leslie Garrier, Milène Gonnier,
20 Barbara Hanse, Morgane Mantelli, Maelys Martin, Cynthia Olivier, Laurène Plante, Chloé
21 Robic, Lisa Rossig, Camille Viaud.

22 **Competing interest**

23 Authors patented antibodies against various pathogens administered before 24 hours of age
24 or between 24 hours and up to 90 days of age in the dog to improve dog health

1 (W02015004181). They designed and scientifically evaluated PuppyProTech - colostrum
2 alternative (Royal Canin, Aimargues, France).

1 **Legends**

2 Figure 1: Pattern of immunoglobulins G, M and A concentrations in puppies' blood. $n=57$
3 Beagle puppies from one kennel, with free suckling. Mean \pm standard deviation. ELISA assay
4 (method described in Chastant-Maillard et al. 2012).

5 Figure 2: Heterogeneity of passive immune transfer (evaluated through blood IgG
6 concentration at Day 2 of age) inter and intra litter. $n= 54$ Beagle puppies from 9 litters from
7 one kennel, with free suckling. The horizontal line indicates the threshold defining failure of
8 passive immune transfer (2.3 g/L). In Litters 5, 6 and 9, all puppies reached a sufficient passive
9 immune transfer; in Litter 4, all were in failure of passive immune transfer; within Litter 1 and
10 7, passive immune transfer was heterogeneous, some above, others below the threshold.

11 Figure 3: Frequency of suckling (in % of suckling time) of each mammary gland during the first
12 24 hours of life. Suckling behavior of 35 Labrador puppies followed by visual observation.

13 Figure 4: Theoretical estimation of the minimal IgG concentration in colostrum for appropriate
14 passive immune transfer.

15 [1] With a blood volume equivalent to 7% body weight and a hematocrit of the newborn
16 puppy at 50%, the total volume of serum within a puppy is 3.5 milliliters for 100g body weight
17 ($100g \times 7\% \times (1-\text{hematocrit})$).

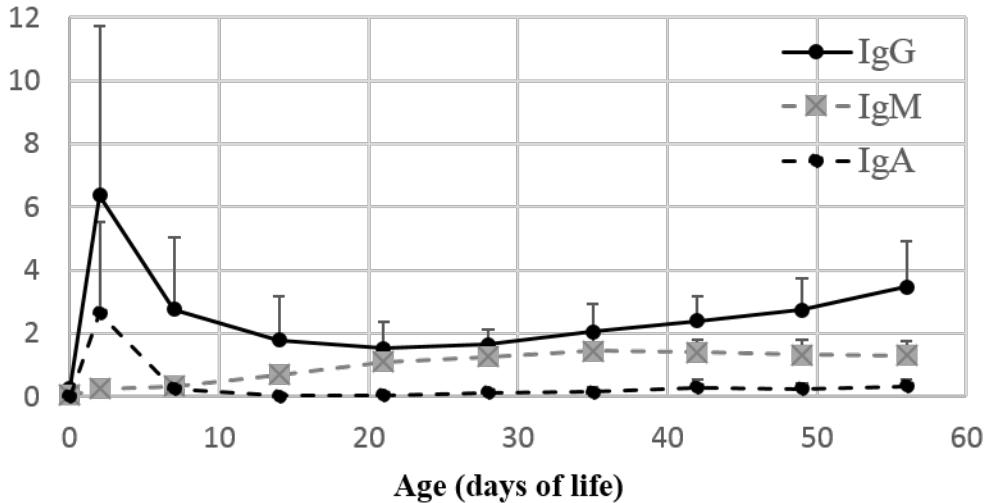

18 [2] The minima serum concentration to be reached by the puppy at two days of age is 2.3
19 g/l, representing an absorbed IgG amount of 8.05 mg ($2.3 \times \text{serum volume}$).

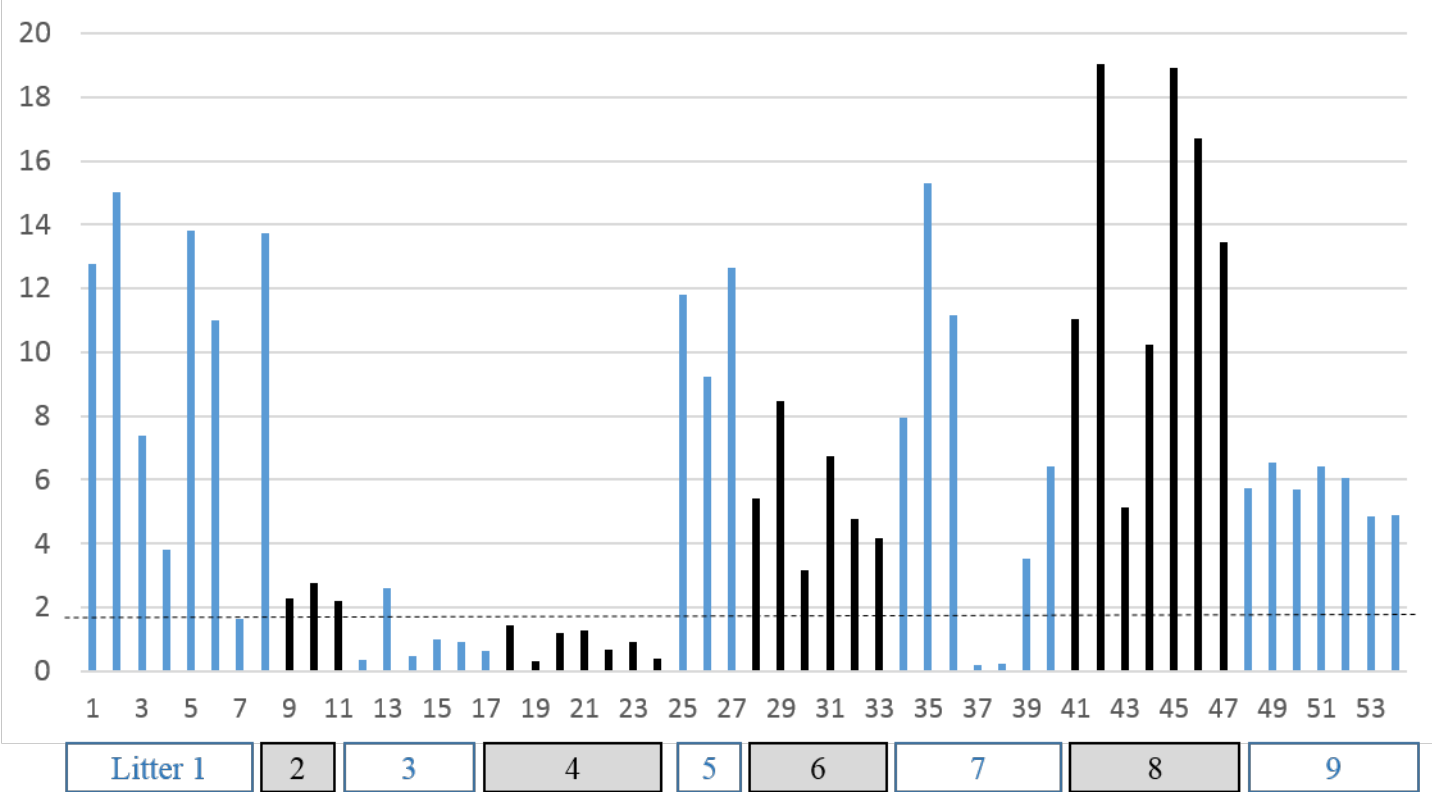

20 [3] The IgG absorption rate was 30% in average between birth and 8 hours of life
21 (Chastant-Maillard et al. 2012). An 8.05 mg absorbed amount corresponds to 26.8 mg ingested
22 IgG.

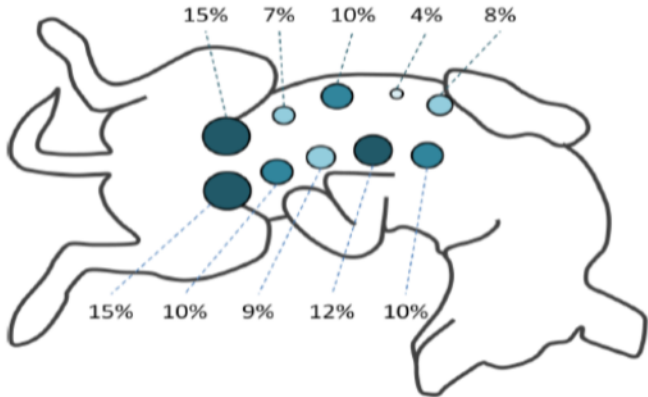

23 [4] A puppy ingests 4 ml/100g body weight and performs 2 meals over the period of
24 intestinal permeability: circulating IgG are thus absorbed from 8 ml colostrum per 100g body
25 weight.

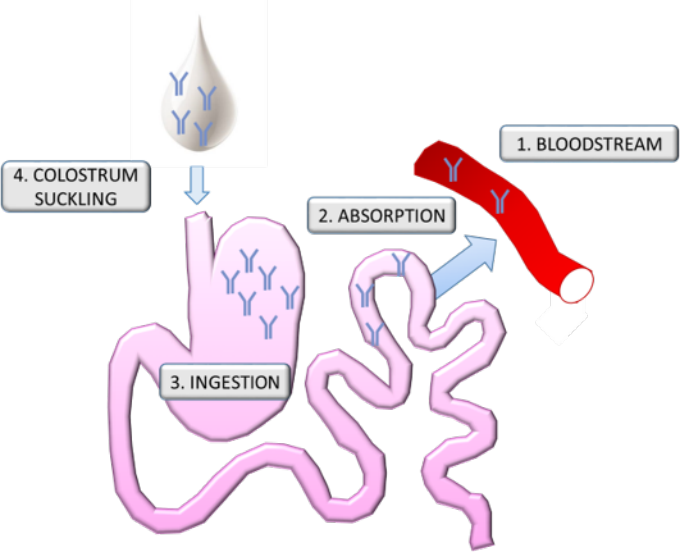

1 [5] The minimal colostrum concentration is 3.4 g/l (ingested IgG x 1000 / 8).
2 Figure 5: CPV2-specific antibody titers (histogram) and fecal viral loads (squares at Day39, 45,
3 53 of age). Puppies ($n=79$ from various breeds within one kennel) were classified in two groups
4 depending on their titer at Day2 (hemagglutination inhibition): 45 puppies with HI titer > 1:160
5 (black), 34 puppies with HI \leq 1:160 (grey). The protective titer is 1:80. Viral load was evaluated
6 by RT PCR (significant above 10^2 copies/ml). NeoCare unpublished data. Methods are
7 described by Mila et al. (2014b).
