15 Abstract

Reliable human health risk assessment associated with chlorinated paraffins (CPs) exposure is limited 16 by the lack of data on the fate of this complex family of contaminants. To gain knowledge on the 17 accumulation and distribution of CPs in biota after ingestion, laying hens were dietary exposed to 18 19 technical mixtures of short- (SCCPs), medium- (MCCPs), or long-chain (LCCPs) CPs of various chlorine 20 contents during 91 days, at 200 ng/g of feed, each. Adipose tissue, liver, muscle and serum were 21 collected at the steady-state, along with excreta. All C10-C36 CPs were detected in liver. However, 22 differences were observed in CP distribution: LCCPs high %Cl were retained in the liver; LCCPs low %Cl 23 circulated through the serum and were distributed in the different compartments, but were mostly 24 excreted through the eggs; SCCPs and MCCPs were found in all tissues at similar levels. Finally, a mass 25 balance indicated a potential for biotransformation. 26

chlorinated paraffins; homologue; distribution; accumulation ratio; dietary exposure; persistent
 organic pollutant

32 1. Introduction

Chlorinated paraffins (CPs), a family of polychlorinated *n*-alkane chains $(C_xH_{2x+2-y}Cl_y)$ with varying chain length and chlorination degrees in the range 30-70% *w/w*, have been used since the late 1970s in many industrial applications such as lubricants in metal-working fluids, flame-retardants and plasticisers

36 (European Food Safety Authority (EFSA) panel on contaminants in the food chain (CONTAM), 2020).

37 Consequently, CPs are produced in large volumes (estimated at 1,000,000 tonnes per year, Glüge et al., 2016). Unfortunately, part of those CPs are released during production, uses and improper disposal 38 39 of polymeric products containing these additives (Glüge et al., 2016). Thus, the CPs environmental 40 levels usually surpass most of the levels of other halogenated contaminants such as 41 polychlorobiphenyls, organochlorine pesticides or dioxins (Zhou et al., 2018; Krätschmer et al., 2019; 42 Niu et al., 2020). CPs have been reported in most environmental compartments, such as air (Niu et al., 43 2020), water (X.-T. Wang et al., 2019), soil (Aamir et al., 2019), sediment (Chen et al., 2011), biota (Yuan 44 et al., 2019), food (Harada et al., 2011; Lee et al., 2020) and even human matrices (Y. Wang et al., 45 2018). The ubiquity of CPs in the environment make them chemicals of concern, notably because they 46 share similar physio-chemical properties with other halogenated contaminants that are considered 47 hazardous for human health.

48 CPs are sub-categorised into short-chain CPs (SCCPs, C₁₀-C₁₃), medium-chain CPs (MCCPs, C₁₄-C₁₇), and 49 long-chain CPs (LCCPs, C≥18). SCCPs were classified as possibly carcinogenic to humans in 1990 by the 50 International Agency for Research on Cancer (IARC working Group on the Evaluation of Carcinogenic 51 Risk to Humans, 1990), and were later shown to cause chronic toxicity to marine species and mammals 52 (X. Wang et al., 2019). As a consequence, they have been phased out in Europe and North America 53 (European Union, 2006; Government of Canada, 2009; United States Environmental Protection Agency 54 (US EPA), 2015) since the 2010s and included in the Annex A of the Stockholm convention in 2017 (Conference of the Parties of the Stockholm Convention, 2017). However, there is a lack of toxicity and 55 toxicokinetics data on MCCPs and LCCPs, though recent occurrence studies on terrestrial and marine 56 57 ecosystems show their potential for bioaccumulation (Yuan et al., 2019). Recently, the EFSA published a scientific opinion on CPs concluding that risk assessment in Europe was hardly feasible, based on the
few submitted toxicological and occurrence data (EFSA CONTAM panel, 2020) at the time of their
evaluation. In particular, they emphasised the need for further information on the influence of the
chain length and the chlorination degree of CPs on their toxicokinetics in humans and experimental
animals.

63 To date, the few published toxicokinetics experiments focused on SCCPs and MCCPs mainly. In rodents, ¹⁴C-labelled SCCPs have been reported to be distributed primarily in fat, liver, bile and egg yolks 64 65 (Biessmann et al., 1982, 1983). The authors also showed that lower chlorinated compounds could 66 undergo degradation to CO₂, whereas the higher chlorinated compounds could not. Later, Fisk et al. 67 (1998) showed accumulation of SCCPs and MCCPs congeners in dietary exposed rainbow trout. In their study, the depuration half-lives varied from 5 to 53 days depending on the octanol-water partition 68 69 coefficient (K_{ow}) and carbon chain length, indicating an influence of the homologue structure on the 70 accumulation potential. More recently, Geng et al. (2016) observed SCCPs absorption and depuration 71 in rats after a single-dose exposure. Alike other persistent organic pollutants, SCCPs distributed in 72 tissues sensitive to the chlorine content. These studies demonstrated well the influence of the 73 homologue structure on the bioaccumulation but were limited to C₁₀-C₁₄ chain lengths. In parallel, one 74 study on SCCPs, MCCPs, and LCCPs in exposed aquatic invertebrates via contaminated water and feed revealed the strong potential of LCCPs for accumulation (Castro et al., 2019). However, contaminants 75 76 have been shown to feature diverse accumulation behaviours in aquatic or terrestrial species (Sun et 77 al., 2017). It was therefore of particular interest to extend the knowledge on the toxicokinetics of 78 SCCPs, MCCPs and LCCPs at a homologue level on terrestrial vertebrates.

In the present study, the laying hen was selected as model organism, as it is a widely distributed farmed animal around the globe. Two previous experiments on hens confirmed the accumulation of SCCPs in abdominal fat, liver and kidney, although the relative concentration in the tissues did not follow the same trends (Ueberschär et al., 2007; Sun et al., 2017). In a previous work (Mézière et al., 2021), we exposed laying hens to an exposure mixture of CPs with various chain lengths and chlorination degrees,

84 at environmentally relevant levels (5×200 ng/g ww, Dong et al., 2019). Substantial amounts of CPs 85 were found in eggs, suggesting that CPs could be absorbed and distributed in laying hens. In this study, 86 we hypothesised that this distribution would be dependent on the homologue formula. We thus 87 collected various tissues and fluids (muscle, liver, fat, serum, and the rest of the carcass) at days 77 88 and 91, days at which we believed the steady-state was reached. Additionally, excreta (faeces + urine) 89 was collected to attempt a mass balance. The results provide valuable data on bio availability and 90 distribution of CPs in the hens. In particular, to our knowledge this is the first time that LCCPs fate in 91 terrestrial birds has been reported.

92

93 2. Material and methods

94 2.1. Chemicals

95 The chemicals used in this study, including the five CP technical mixtures for feed fortification, internal 96 and external standards, and other chemicals and solvents used during the sample preparation are 97 detailed in the supplementary data (Section S1) and are the same as in our previous study (Mézière et 98 al., 2021). The five CP technical mixtures cover a range of chain lengths and chlorine contents: SCCPs 99 low %Cl (Chlorowax[™] 500C SCCPs, low chlorine content), SCCPs high %Cl (Paroil[™] 179 HV, SCCP, high 100 chlorine content), MCCPs (I-42, low chlorine content), LCCPs low %Cl (Unichlor[™] 40-90, LCCP, low 101 chlorine content) and LCCPs high %Cl (CPW 100, LCCP, high chlorine content) (Figure S1).

102

103 2.2. Feed, experimental design and sampling

104 The present work completes a kinetic study on CPs transfer to eggs of laying hens; details of feed and

105 experimental design have been described previously (Mézière et al., 2021).

106 Briefly, a feed basis containing all required nutrients for laying hens was pelleted with non-spiked or

spiked rapeseed oil (Table S1), for control and exposed groups respectively, with a target concentration

108 in spiked feed of 200 ng/g ww for each of the five technical mixtures cited above (§2.1).

109 The animal experiment was ethically approved by the French authorities under number APAFIS#17145-110 2018101712299769v2 and was conducted in an appropriate facility (https://doi.org/10.15454/1.5572326250887292E12). After a one-month acclimation in individual 111 112 cages, 25-week old laying hens (Isa Brown) were randomly separated into control and exposed groups 113 (day 0) (Figure S2a). The control (n=6) and exposed (n=13) hens of interest for the present work 114 weighed 1656 ± 81 g at day 0. They were fed with the corresponding feed (spiked or non-spiked) during 115 91 days. Feed intake was recorded weekly, by weighing feed allowance and refusals. Both groups 116 ingested 110 ± 12 g daily of feed along the experiment.

Hens were weighed and slaughtered after a 12 h fast, on day 77 (5 exposed) or day 91 (6 controls and 8 exposed), by electrical stunning followed by carotid artery section. Blood was collected and serum separated after coagulation. Then, hens were plucked and the liver, abdominal fat and muscles of the left leg (thigh and drumstick) were collected and weighed. The rest of the carcass (blood clot included) was weighed and kept as well. In addition, the excreta (faeces + urine) produced during the last 14 days of individuals slaughtered at day 91 were collected and mixed. All samples were stored at -20 °C until analysis.

124

125 2.3. Extraction and Clean-up

Carcasses were ground and homogenised in an appropriate facility. Then, carcasses, livers and muscles
were lyophilised. Excreta were dried in oven at 60 °C during 2 days (Figure S2b).

128 CPs were co-extracted with lipids from 1.5, 2, 5 and 1 g of dry carcass, liver, muscle and excreta, 129 respectively, using pressurised liquid extraction (SpeedExtractor E-914/E-916, Büchi, France) with a 130 mixture of toluene/acetone (7:3, v/v, 3 static cycles, 120 °C, 100 bar). For adipose tissue, 0.5 g of liquid 131 fat was directly aliquoted. ¹³C- γ -Hexabromocyclododecane (¹³C- γ -HBCDD, 5 ng) was added to lipidic 132 extracts as internal standard, and fat contents were determined gravimetrically. Serum (10 g) was 133 extracted by liquid-liquid extraction after adding the internal standard. Proteins were precipitated with 134 dipotassium oxalate, and extraction was performed with two cycles of methanol-diethyl etherpetroleum ether mixtures and decantation. The two organic phases were filtered and reassembled.
Lipid classes (triglycerides, esterified and free cholesterol, phospholipids) in serum were determined
according to 4 enzymatic kits (Biolabo, Maizy, France) (Marchand et al., 2010) and the total lipid
content was then calculated as their sum.

Lipidic extracts were purified according to Mézière et al. (2021) using packed columns containing acidic silica gel and deactivated Florisil. The extracts were reconstituted in 25 μL of acetonitrile containing d_{18} -β-HBCDD (0.2 ng/μL) as external standard.

142

143 2.4. Data acquisition and data-treatment

The instrumental set-up was identical to that of Mézière, Cariou, et al. (2020) and Mézière et al. (2021). In short, sample extracts were analysed by reverse phase liquid chromatography-high resolution mass spectrometry fitted with an electrospray ionisation source. A dichloromethane/acetonitrile mixture (1:1, v/v) was added post-column to enhance the formation of the monitored [M + Cl]⁻ adduct ions, from C₁₀Cl₄ to C₃₆Cl₃₀. Corresponding signals were extracted (±5 ppm) and integrated using the open source programming *R* environment. After application of identification criteria (isotopic ratio and minimum intensity), signals of the quantifier ions were normalised by their isotopic contributions.

151

152 2.5 Quantification and accumulation calculations

153 Quantification of the five CP subcategories studied (Figure S1) was performed by external calibration 154 similarly as in our previous work on eggs Mézière et al. (2021). A serial dilution (9 points) of the five technical mixtures was performed within the dynamic range of 0.1-15 ng/ μ L for each technical mixture. 155 156 After control of the instrumental performances with the external standard, the areas of homologues 157 were summed per technical mixtures. Then, the ratio of CP sum area to the internal standard area was correlated to the ratio of the corresponding technical mixture concentration to the internal standard 158 159 concentration. It should be noted that some homologues overlapped between the SCCPs and the 160 MCCPs (Figure S1, C13 to C15 homologues). However, since we used the same solutions for exposure and quantification, the resulting calibration curves remain representative of the CPs in the samples,
 overlap included. The dynamic range was divided into two sub-ranges (0.5-2 and 2-15 ng/µL) which
 fitted adequately with linear curves.

The similarities between the CP homologue response patterns of the calibration solution and the tissues was assessed using a least-square approximation with a non-negative constraint (*lsqnonneg* function, *pracma* package, open source programming *R* environment). The profiles were considered as a good match when the parameter *a* of the equation $[S] = a \times [M] + b$ was close to 1 (± 0.1), where [S] and [M] are the vectors of the homologues detected in the sample and the corresponding technical mixture, respectively.

170 Considering that the steady-state was reached, the accumulation ratios (*AR_{CP subcat.}*) in the samples
171 (S) could be calculated in exposed hens according to equation 1:

172
$$AR_{CP \ subcat.} = \frac{C_{CP \ subcat.}(S)}{C_{CP \ subcat.}(feed)}$$
 Eq.1

where $C_{CP \ subcat.}(S)$ and $C_{CP \ subcat.}(f \ ed)$ are the concentrations of the CP subcategories in the tissue (ng/g lw) and the spiked feed (ng/g ww), respectively.

175 The concentrations of each homologue in the technical mixture was not known, thus the homologue 176 concentration could not be calculated. However, we followed that same reasoning as detailed in our 177 previous work (Mézière et al., 2021) to calculate homologue-level accumulation ratios. Indeed, the 178 concentration of a homologue n, x can be expressed according to the exposure mixture concentration at which the same homologue n, x would have the same relative intensity $(A_{n,x}/A_{IS})$ and the 179 180 contribution of the homologue to this exposure mixture (although not known). As the spectrometric 181 response of the homologue is considered to be the same in the tissues or the feed, this term can be eliminated from the equation and the accumulation ratio can be calculated using the ratio of areas of 182 183 the homologue in the feed and in the tissues. The final expression can be written as follows:

184
$$AR_{n,x}^{S} = \frac{Q_{IS}^{S}}{Q_{IS}^{feed}} \times \frac{SS^{feed}}{SS^{S}} \times \frac{f_{n,x}^{-1}(\frac{A_{n,x}^{S}}{A_{IS}^{feed}})}{f_{n,x}^{-1}(\frac{A_{n,x}^{feed}}{A_{IS}^{feed}})}$$
Eq. 2

185 where $AR_{n,x}^{S}$ is the accumulation ratio of the homologue n, x, Q_{IS}^{S} and Q_{IS}^{feed} are the quantity of 186 internal standard in the hen tissue or the feed, respectively, SS^{S} and SS^{feed} are the corresponding 187 sample sizes, respectively, $f_{n,x}^{-1}$ corresponds to the calibration curve of the exposure mixture solutions, 188 and $A_{n,x}^{S}, A_{IS}^{feed}, A_{IS}^{feed}$ are the signal areas of the homologue n, x or the internal standard (*IS*) in 189 the tissue (*S*) or the feed, respectively.

190 The $A_{n,x}^S$, could be calculated for each exposed individuals, respectively. Mean $A_{n,x}^S$ were calculated 191 for homologues observed in at least 4 individuals (\geq 50% detection frequency) only.

192

193 2.6 QA/QC

194 All glassware was heated at 400 °C during 4 h before use. Tissues and excreta were prepared and 195 analysed in distinct batches, along with a total of 25 procedural blanks and 20 quality control samples 196 (QCs) when considering feed and egg yolk batches from the previous study as well. Traces of SCCPs low %Cl and MCCPs were found in all blank extracts at concentrations varying between 2-17 and 5-33 197 198 ng/sample, respectively (Table S2). Traces of LCCPs low %Cl were found as well in some batches at 199 concentrations up to 32 ng/sample. Thus, homologue relative areas in samples were corrected from 200 the corresponding homologue relative area in the blank prior to quantification. Recovery was 201 evaluated during the previous study with a QC (mixture of exposed eggs from day 32 and day 88, spiked 202 with LCCPs high %Cl at the level of 250 ng/g), and varied between 66% and 151% depending on the CP 203 technical mixture. The variability intra-batch was considered acceptable (12-29%, Table S3). However, 204 the inter-batch variability was slightly higher (26-41%), showing that there is still room for improving 205 quantitative determination, although recent interlaboratory assays showed great progress on this 206 matter (Krätschmer and Schächtele, 2019; Mézière, Krätschmer, et al., 2020). Method detection limits 207 were not calculated (Mézière et al., 2021) and the limit of quantification (LOQ) was defined as the lowest point of the external calibration (0.1 ng/µL). This corresponded to 5 ng/g lw for adipose tissue, 208 209 liver, muscle, carcass, to 25 ng/g lw for serum, and to 2.5 ng/g dw for excreta.

211 **3. Results and discussion**

The body weight of hens (day 77 and day 91) at slaughter did not significantly differ between the control (1646 \pm 84 g) and the exposed (1661 \pm 82 g) groups (P>0.1) (<u>Table S4</u>), nor between exposed hens slaughtered at day 77 or day 91 of the exposure. Additionally, the feed ingested daily was constant over time (P>0.1), and reached 66 \pm 5 g/kg bw/day. Thus, all exposed hens were exposed to the same amount of CPs over the experiment.

As previously reported (Mézière et al., 2021), the control batch of the feed contained residues of SCCPs, MCCPs and LCCPs, likely originating from seed ingredients. Hence, the total exposure of the individuals considered in the present study corresponded to about 24, 26, 27, 22, and 34 μg/day of SCCPs low %Cl, SCCPs high %Cl, MCCPs, LCCPs low %Cl and LCCPs high %Cl, respectively.

221

222 3.1. CP mix level concentrations, AR and mass balance

223 <u>3.1.1. Concentrations</u>

Concentrations of CPs in the different tissues were constant between day 77 and day 91 of exposure
 (Figure S3), suggesting that the steady-state was reached before the end of the experiment. This is in

226 line with the previously estimated time to reach the steady-state in eggs (~14 days, Mézière et al.,

227 2021). For the following discussion, only concentrations calculated at day 91 are considered.

228 SCCPs and MCCPs were detected in all matrices, confirming that those CP subcategories permeated 229 through the gastro-intestinal tract, transferred into blood and reached the different tissues (Figure 1, 230 Table S5). In excreta, SCCPs low %Cl concentrations were lower than for the two other CP 231 subcategories, suggesting a higher bioavailability compared to the other CP subcategories. SCCPs and 232 MCCPs concentrations were relatively similar between the different matrices, although the muscle and 233 serum appeared less contaminated and were close to or below the LOQ. This even distribution suggested that the distribution of SCCPs and MCCPs in different matrices may be driven mostly by 234 hydrophobic interactions rather than more specific interactions (justifying a concentration reporting 235 236 in lw). This is supported by previous experiments on SCCPs in laying hens and broilers (Ueberschär and

Matthes, 2004; Ueberschär et al., 2007) which also concluded in a lipid content-related accumulation in tissues (fat > liver and yolk > muscle). Interestingly, SCCPs low %Cl were detected at lower levels compared to SCCPs high %Cl and MCCPs. SCCPs with lower chlorine content have been shown to degrade down to CO₂, whereas SCCPs high %Cl did not (Biessmann et al., 1982, 1983). The lower concentration of SCCPs low %Cl may come from a higher potential for biodegradation compared to CPs with higher Cl content and longer chains.

LCCPs low %Cl were also detected in all matrices, revealing their circulation in the hens. However, 243 244 concentrations were similar between the liver and serum, as well as in eggs (Mézière et al., 2021), but 245 were much lower in adipose tissue and muscle (Figure 1). This indicates a different mechanism of 246 distribution depending on the matrix for this type of CPs. It was already discussed for other 247 contaminants that the distribution is related to the perfusion rate of the tissues homologues (Pirard 248 and De Pauw, 2005), with compounds being firstly distributed into highly perfused matrices, and in a 249 second time reaching tissues of lower perfusion rate such as muscle and adipose tissue. Hence, it could 250 be hypothesised that with longer chain length, LCCPs reach the tissues of lower perfusion rate more 251 slowly than SCCPs and MCCPs, thus they preferentially accumulate in high perfusion matrices such as 252 eggs while SCCPs and MCCPs are readily accumulated homogeneously in the whole body. A slower 253 distribution of LCCPs may lead to a longer time to reach the steady-state. It would be interesting to 254 monitor the kinetics of CPs accumulation in tissues to investigate this hypothesis, although this was 255 not observed in eggs (Mézière et al., 2021).

Finally, LCCPs high %Cl were detected in a higher level in excreta compared to the other CP subcategories, suggesting a more difficult absorption. If absorbed, they were detected in liver mostly, with traces in eggs (Mézière et al., 2021) and serum (<u>Figure 1</u>). Such high concentration of LCCPs high %Cl suggests that this CP subcategory can also reach the liver *via* the hepatic portal vein, supporting their bioavailability. However, the low concentration in serum indicates that this CP subcategory is retained in the liver or, alternatively, could be excreted *via* bile to the intestine from which it may be

excreted *via* the faeces or reabsorbed. This entero-hepatic cycle has been described for drugs in rats
and dogs (Yesair et al., 1970). To support this hypothesis, analysis of the bile would be beneficial.

264

265 <u>3.1.2. Accumulation ratios</u>

266 Accumulation ratios (ARs) were estimated in each matrix using the mean concentrations of CP 267 subcategories in exposed laying hen tissues (when <LOQ) and spiked feed (Table 1, Table S5). For all 268 CP subcategories, ARs were higher for eggs, liver, and serum than for adipose tissue and muscle. This 269 suggests that CPs are distributed preferably in liver and eggs compared to the inner tissues. 270 Additionally, the ARs increased in the order SCCPs low %Cl < MCCPs < LCCPs and SCCPs low %Cl < 271 SCCPs high %Cl for eggs, liver, and serum. ARs of the SCCPs high %Cl were compared with those previously reported by Ueberschär et al. (2007), where laying hens were dietary exposed to similar 272 273 levels of SCCPs 60% Cl (140 ng/g ww feed) during 7 weeks, with a similar feed consumption (107-115 274 g/day). SCCPs accumulated more in abdominal fat (2.5 times) but less in eggs (2.5 times) compared to 275 the present experiment. These differences could be explained by several hypotheses, including the 276 influence of a different hen strain ("Lohmann selected leghom"), different chlorine content, and a 277 cocktail effect arising from the simultaneous exposure to several mixtures in the present study.

Kan and Meijer (2007) proposed a classification of chlorinated pesticides according to the
accumulation ratio. According to this basis, the CPs would be classified as low to moderately
accumulative.

281

282 <u>3.1.3. Mass balance</u>

Considering that steady-state was reached in the carcass and sampled matrices by day 77 (Figure S3),
a mass balance between CP input (feed, from Mézière et al., 2021) and monitored outputs (excreta,
egg) was performed from day 77 to day 91. Average dried matter and lipid contents of samples are
provided in <u>Table S6</u>.

287 Excreta released 0.8, 2.0, 1.9, 2.0, and 4.3 µg/day of SCCPs low %Cl, SCCPs high %Cl, MCCPs, LCCPs low 288 %Cl and LCCPs high %Cl, respectively (Table S7), corresponding to 3%, 8%, 7%, 9%, and 13% of the 289 ingested CP subcategories, respectively (Figure 2). Meanwhile, the egg yolks released 0.2, 0.8, 0.5, 7.0 290 and 0.13 µg/day of the five categories, corresponding to 1%, 3%, 2%, 32%, and 0% of the ingested CP 291 subcategories, respectively. SCCPs low %Cl were the least released in the excreta at the steady-state, 292 while the LCCPs high %Cl were the most released in the excreta, because of physical properties 293 discussed earlier. Meanwhile, CPs proportion in eggs were lower compared to excreta, except for 294 LCCPs low %Cl which featured high absorption but also a high transfer to eggs compared to SCCPs and 295 MCCPs.

More importantly, the mass balances of CPs were underestimated from -59% for LCCPs low %Cl to -96% for SCCPs low %Cl (Figure 2, Table S7). Plausible unchecked excretion routes include feathers and preen oil, as observed for other contaminants (Rutkowska et al., 2018). Also, it should be noted that excreta were collected after 14 days. Thus, potential degradation of CPs in this time period from contact with microorganisms present in the excreta or air may also have impacted the mass balance.

301 However, we hypothesise that CPs are subjected to biotransformation. One recent study on in vitro 302 enzymatic transformation with human liver microsomes showed a decreased of the CPs 303 concentrations down to -97% depending on the enzyme used and CPs technical mixture (He, 2019). 304 The authors suggested that CPs may degrade into shorter chain CPs, and observed the formation of 305 CO-CPs products among four targeted biotransformation products. In our study, the CP response 306 patterns did not shift towards shorter chain lengths, thus we considered that biotransformation 307 products would be more plausible. Hence, we further explored the raw data acquired from egg, liver 308 and carcass samples, using the post-acquisition data treatment software HaloSeeker 1.0 developed by 309 Léon et al. (2019). Unfortunately, although CPs were clearly identified, no other polychlorinated series 310 of signals could be observed in these high resolution mass spectrometry data sets. It should be 311 however noted that the sample preparation was specifically developed for CPs, and biotransformation 312 products may have been eliminated during one of the purification steps of the process. Further

characterisation of the CP metabolism should thus be performed in order to better apprehend the
mass balance of CPs in experimental animals, possibly with implementation of untargeted analytical
strategies from sample preparation to data treatment (Pourchet et al., 2020).

316

317 3.2. Homologue response profile and homologue accumulation ratio

318 <u>3.2.1 Homologue response profiles</u>

CPs bioavailability and accumulation were investigated more finely at the homologue level. First, CP patterns between the various laying hen matrices and the exposure mixture were compared for the exposed group (Figure 3) and control group (Figure S4). The surfaces of the CP patterns in the feed matched closely the exposure mixture, confirming that the spiking was performed correctly. However, shifts of the response patterns were observed in the matrices.

324 SCCPs and MCCPs were present in the 2D-map representations of every matrices and their surfaces 325 matched the one of the exposure mixture relatively well for excreta, liver, and carcass, but seemed 326 shifted towards higher chlorinated homologues in adipose tissue, serum and muscle. This shift was 327 discussed in our previous work on CPs in laying hens eggs, and was correlated to a homologue-328 dependant accumulation ratio, caused by higher octanol-water partitioning coefficients (Kow) (Mézière 329 et al., 2021). SCCPs low %Cl seemed lost in the 2D-representation of liver and serum, although they 330 were detected in both matrices. In liver, this is explained by the surface calculation which includes all 331 subcategories: the contribution of SCCPs low %Cl to the whole pattern of liver is too small compared 332 to the other subcategories. The predominance was marked by LCCPs low %Cl and LCCPs high %Cl. In 333 serum, SCCPs low %Cl were absent from the 2D-blank representation of the profiles after blank 334 subtraction.

LCCPs low %Cl surfaces underwent the same shift towards higher chlorinated homologues, but also according to the chain length in the liver (C_{20} to $C_{>36}$). Oppositely, they were not represented in the 2Dmap of muscle and only shorter chain lengths were represented in adipose tissue (C_{20} to C_{30}). This suggests that LCCPs low %Cl homologues are distributed differentially in the hens. The longest chain lengths tended to be retained in the liver, similarly as for the LCCPs high %Cl technical mixture, while
the shortest chain lengths were closer to the SCCPs/MCCPs behaviour.

Finally, most of the LCCPs high %Cl were observed in the liver and the excreta. In liver, only homologues up to C₃₀Cl₂₄ were detected, suggesting a that the longer/higher chlorinated homologues couldn't pass through the gastro-intestinal barrier. However, traces of the smallest homologues of this CP pattern were detected in serum and carcass, indicating that this CP subcategory should not be discarded too rapidly.

346 It should be noted that the quantification of the present study, based on external calibration using the 347 exposure mixtures, was sensitive to the similarity of the response patterns between the tissues and 348 the exposure mixture. Indeed, the instrumental response of the technical mixture was shown to be 349 dependent on the overall chlorine content and chain length of the mixture (Mézière, Cariou, et al., 350 2020). This similarity was thus assessed to control the quantification accuracy by calculating a factor 351 between the tissues and the exposure mixture that would be need to make the patterns match. In 352 those conditions, $a = 1 (\pm 0.1)$ would mean a perfect match, as demonstrated with the feed (Table 2). 353 The best match was reached in the excreta. This was attributed to the release of a part of CPs into 354 excreta directly without going through the gastro-intestinal tract, thus with only limited differentiation 355 based on homologue structure and chemical properties. The weakest match was observed for SCCPs 356 and MCCPs in the serum, which was attributed to undetected homologues on the fringe of the CP 357 subcategory due to low levels in this matrix. For the other matrices, the least-square approximation 358 returned medium values.

According to the non-negative least-square approximation results, quantification can be considered accurate for feed, excreta, adipose tissue, and carcass. It may however suffer more deviation to the true value for liver and muscle, and be considered as tentative only for SCCPs and MCCPs in serum.

Nevertheless, CP bioavailability and distribution in the hens was found homologue-dependant, which resulted in shifted response patterns compared to the exposure mixture. These results may help to refine the current knowledge on CPs fate in animals.

365

389

366 <u>3.2.2 Homologue-level accumulation ratio</u>

The accumulation ratios per homologue ($AR_{n,x}^S$, Eq. 3) were determined using the relative signal in 367 each considered matrix (n=8 individuals) and in the feed (mean of triplicate analysis). The mean and 368 uncertainty of $AR_{n,x}^S$ varied greatly, depending on the homologue and the tissue, from <1 to 103 for 369 370 the mean (Figure 4). The liver featured the highest accumulation ratios, which increased with chlorine 371 content and chain length up to an optimum reached for the C₃₂Cl₁₁ homologue (Figure 4). For a fixed number of chlorines the highest $AR_{n,x}^{liver}$ were reached for 32 to 36 carbons in the chain, with the 372 373 optimum tending to decrease with increasing chlorine number (Table S8). For a fixed number of 374 carbon, optimums were reached for almost each chain length, with a broad range of chlorine numbers 375 (from $C_{18}Cl_9$ to $C_{27}Cl_{20}$). Interestingly, the $AR_{n,x}^{liver}$ of the LCCPs low %Cl homologues increased with the 376 chlorine content, while those of the LCCPs high %Cl homologue decreased. This strongly suggests that 377 optimums are reached for homologues in-between, which were not included in the exposure mixture. $ARs_{n,x}^{serum}$ followed similar trends as in liver, i.e. a positive correlation between the $ARs_{n,x}^{serum}$ and the 378 379 chlorine number and chain length up to an optimum reached for C₃₂Cl₁₀. However, the values diverged less ($ARs_{n,x}^{serum} = <0.1-13$) and only three $ARs_{n,x}^{serum}$ could be calculated for LCCPs high %Cl with the 380 381 selected restriction (≥50% frequency) (Figure 4, Table S9). For a fixed number of chlorines, the 382 optimums were reached for shorter chain lengths (C₂₆ to C₃₂) and tended to increase with increasing 383 chlorine content, oppositely to liver. For a fixed number of carbons, optimums were obtained for 384 homologues with Cl₉-Cl₁₁. Hence, liver retained more the higher chlorinated and of higher chain length 385 homologues. The trend obtained for the serum and the liver are close to the one obtained previously for the eggs (Mézière et al., 2021), suggesting an important interaction between the three matrices. 386 The muscle and adipose tissues behaved differently. In the muscle, the $ARs_{n,x}^{muscle}$ did not increase 387 towards an optimum but rather formed a ridge in the direction of $C_{18}Cl_9$ to $C_{11}Cl_{11}$ (Figure 4, Table S10), 388

390 a positive influence on the accumulation ratio, but are hindered by another parameter such as the

with lower accumulation ratios (0-8). This indicated that both chain length and chlorine content have

391 molecular size, as the m/z of the homologues on the ridge are centred around 600. This is also supported by the rare $ARs_{n,x}^{muscle}$ calculated for LCCPs low %Cl, that highlighted the low detection 392 frequency of this CP subcategory in muscle. Last, the $ARs_{n,x}^{adipose\ tissue}$ values were even lower and 393 394 remained relatively stable (<0.1-0.9, Figure 4, Table S11), suggesting low accumulation in this tissue. 395 Several maximums could be observed: one around C₁₂Cl₁₀, one around C₁₉Cl₇ and the other forming a 396 ridge between $C_{26}Cl_5$ and $C_{30}Cl_9$. These lower accumulation ratios with distinct trends for muscle and 397 adipose tissue suggest a different affinity of CPs for the inner organs of the laying hens compared to 398 the liver, serum and eggs, that may take into account not only the CPs hydrophobic interactions but 399 also specific interactions such as protein binding. To date, these specific CP interactions have been 400 poorly studied and should be further investigated.

As previously discussed for LCCPs low %Cl (§3.1.1), it is not surprising that the liver, serum and eggs give similar results, as large flows of metabolites pass from the liver to the eggs via the bloodstream for a laying hen. On the other hand, in an adult hen, the growth of muscle and fat tissue is rather limited and there is little flow of metabolites, explaining the similar results for these two tissues.

405 To our knowledge, only three studies have reported CP dietary exposure of birds. Ueberschär and 406 Matthes (2004) investigated SCCPs fate in broilers and Ueberschär et al. (2007) exposed laying hens to 407 SCCPs, but neither articles discussed at the homologue level. Recently, Sun et al. (2020) reported SCCPs 408 homologue accumulation ratios in close-range raised laying hens. Interestingly, the authors reported 409 accumulation ratios decreasing with Kow. We observed the opposite in our study, with homologue 410 accumulation increasing with chain length and degree of chlorination, although the homologue log Kow 411 were not modelled here. However, many variables differed between the two experiments, notably the 412 dietary exposure protocol (soil + feed, uncontrolled versus feed, controlled). Moreover, it should be 413 noted that SCCPs K_{ow} varied between 5 and 6.6 in the study of Sun et al. (2020), whereas the K_{ow} range 414 was larger in our study (up to ~12 for LCCPs). Thus, we believe that this study completes the current 415 knowledge on homologue-level accumulation behaviour in birds.

417 **4. Concluding remarks and perspectives**

418 The present study aimed to provide a preliminary investigation on the distribution behaviour of CPs in 419 exposed laying hens, depending on their chain length and chlorine number. The exposure of laying 420 hens to five CPs technical mixtures of different chain lengths (SCCPs, MCCPs, LCCPs) and degree of 421 chlorination (low versus high) enabled highlighting the bioavailability of all CP subcategories. However, 422 striking differences according to the chain length and degree of chlorination were observed regarding their distribution in the laying hens. Up to a certain chain length and chlorination degree, CPs were 423 424 released from the liver to the serum. However, some homologues (LCCPs high %Cl) were not at all 425 detected in serum, suggesting either retention in liver or release through bile to the intestine. Analysis 426 of this latter matrix would definitely complete the present study. The longest homologues of LCCPs 427 low %Cl and the whole LCCPs high %Cl pattern were directly excreted in the eggs. Meanwhile, SCCPs, 428 MCCPs, and the shortest homologues of the LCCPs low %Cl pattern could reach the internal tissues 429 (muscle and adipose tissue). This observation confirmed the accumulation of SCCPs, and extended it 430 to MCCPs and LCCPs. Additionally, the homologue-level accumulation ratio revealed similar behaviour 431 of CPs in liver, serum and egg, but strong differences in the inner tissues. A depuration study that 432 would provide half-lives for toxicokinetics considerations would complete the present work.

433 More importantly, this study revealed an uneven mass balance between ingested and excreted CPs at 434 the steady-state that suggest biotransformation of all CPs in the laying hens. Although preliminary 435 studies on this matter have begun to emerge in the literature, knowledge on CPs metabolism is scarce 436 and should be targeted in the near future with dedicated protocols to complete the risk assessment 437 related to the exposure to CPs.

606	Figure	captions

607

608	Figure 1. Distribution of the concentrations determined for CP subcategories in laying hen excreta
609	(ng/g dw) and matrices (ng/g lw) at the steady-state. Box plots represent centiles (0, 25, 50, 75 and
610	100). Blue dashed lines represent the LOQ (5 ng/g lw for adipose tissue (AT), liver, muscle, 25 ng/g
611	lw for serum, and 2.5 ng/g dw for excreta).
612	
613	Figure 2. Daily mass balance of CP subcategories between excreta and egg yolk relative to feed input,
614	estimated over a 14 days period at the steady-state.
615	
616	Figure 3. 2D-map comparing 95% of the total areas of the CP patterns from day 91 between the
617	collected matrices for exposed laying hens (blue line) or feed (green line) and the exposure mixture
618	(black dashed line).
619	
620	Figure 4. 3D-representation of the homologue-level accumulation ratios in liver, serum, muscle and
621	adipose tissue after 91 days of exposure.
622	

	SCCPs low %Cl	SCCPs high %Cl	MCCPs	LCCPs low %Cl	LCCPs high %Cl
Egg	0.2*	0.8*/0.3**	0.5*	7.1*	n.c.*
Liver	0.1	0.2/<0.1**	0.4	6.2	3.1
Serum	n.c.	0.6	0.3	7.7	n.c.
Muscle	<0.1	0.1	0.1	0.1	n.c.
Adipose tissue	0.1	0.2/0.5**	0.2	0.1	n.c.

Table 1. Accumulation ratios of CP subcategories in laying hen matrices, according to eq. 1.

* from Mézière et al. (2021); **from Ueberschär et al. (2007); n.c. : not calculated

Table 2. Parameter *a* of the least-squares approximation with a non-negative constraint, of equation

 $[S] = a \times [M] + b$, for the feed and laying hen matrices from the exposed laying hens at day 91

629 compared to the exposure mixture. Bold: a > 0.7.

	feed	excreta	adipose tissue	carcass	liver	muscle	serum	egg (D89)
SCCPs low %Cl	1.03	1.00	0.70	0.74	0.73	0.54	n.c.	0.88*
SCCPs high %Cl	1.02	0.84	0.83	0.93	0.85	0.90	0.53	1.02*
MCCPs	1.03	0.99	0.73	0.76	0.70	0.61	0.36	0.57*
LCCPs low %Cl	1.00	0.96	0.83	0.95	0.63	n.c.	0.80	0.87*
LCCPs high %Cl	1.08	0.96	n.c.	n.c.	0.62	n.c.	n.c.	0.52*

n.c.: not calculated, because levels considered as too low; *from Mézière et al. (2021)
