11 ABSTRACT

12 The fate of nanoparticles (NPs) in soil under relevant environmental conditions is still poorly
13 understood. In this study, the mobility of two metal-oxide nanoparticles (CuO and TiO₂) in
14 contrasting agricultural soils was investigated in water-saturated soil columns. The transport of
15 TiO₂ and CuO-NPs were assessed in six soils with three different textures (from sand to clay)
16 and two contrasted organic matter (OM) contents for each texture. TiO₂ mobility was very low
17 in all soils, regardless of texture and OM content. Mass recoveries were always less than 5%,
18 probably in relation with the strong homo-aggregation of TiO₂-NPs observed in all soil
19 solutions, with apparent sizes 3-6 times larger than their nominal size. This low mobility
20 suggests that TiO₂-NPs present a low risk of direct groundwater contamination in contrasted
21 surface soils. Although their retention was also generally high (more than 86%), CuO
22 nanoparticles were found to be mobile in all soils. This is probably related to their smaller
23 apparent size and low capacity of homo-aggregation of CuO-NPs in all soil solutions. No clear
24 influence of neither soil texture or soil total organic matter content could be observed on CuO
25 transport. However, this study shows that in contrasted agricultural soils, CuO-NPs transport is
26 mainly controlled by the solutes dissolved in soil solution (DOC and PO₄ species), rather than
27 by the properties of the soil solid phase.

29 **Keywords:** Contrasted soils, Nanomaterials, Transfer, Dissolved organic carbon, CDE
30 modelling, Nanoparticles' fate.

31 **Highlights:**

- 32 • Limited mobility of CuO and TiO₂ nanoparticles in contrasted agricultural soils
- 33 • DOM and dissolved P species appear as drivers of soil CuO NPs mobility
- 34 • Lower mobility of TiO₂ nanoparticles than CuO likely due to higher homoaggregation

Introduction

Metal oxide engineered nanoparticles (NPs) are now integral elements of a myriad of consumer and industrial products. Copper oxide (CuO) NPs are widely used in catalysts, superconductors or paints for their biocidal properties (Zhu *et al.* 2004; Ren *et al.* 2009; Keller *et al.* 2013). Titanium dioxide (TiO₂) NPs are commonly incorporated in personal care products, paints or food packaging (Keller *et al.* 2013). As a result, soils are exposed to these components through various exposure routes, which may result in potential risks to human and ecosystems health. Their release into soils can occur during industrial production, landfills, agricultural amendments of sewage sludge, abrasion of materials and accidental spill (Nowack *et al.* 2012). Thus, there appears to be an urgent need to improve our current knowledge of the fate and transport of NPs in soils in order to better assess the risks for groundwater and agricultural soils. Transport of NPs has been extensively investigated in poorly-reactive and well-defined porous media, such as glass beads or quartz sand, but only a few investigations have addressed the transport of metallic NPs in natural soils (e.g. Fang *et al.* 2009, 2011; Cornelis *et al.* 2013; Braun *et al.* 2015; Simonin *et al.* 2016). Soils are porous systems consisting of complex structured assemblages of mineral and organic particles combined with liquid and gaseous phases (Spadini *et al.* 2018). Several soil components such as clay and organic matter (OM) are known to influence the mobility of various pollutants or colloids due to their large reactive surfaces, which can interact with them, thus modifying their physicochemical behavior (Pan and Xing 2012). Some studies have demonstrated the influence of these factors on the aggregation, surface charge and stability of NPs (Fang *et al.* 2009; Thio *et al.* 2011; Zhou *et al.* 2012). Dissolved OM is known to promote NPs dispersion and potentially their mobility in simple porous media (Ben-Moshe, Dror and Berkowitz 2010; Thio, Zhou and Keller 2011; Simonin *et al.* 2015), while clay particles can destabilize positively and negatively charged NPs and thus decrease their mobility (Zhou *et al.* 2012). In addition, these processes are strongly

influenced by the chemistry of soil solution, such as pH, ionic strength and electrolytes such as inorganic ions (Wang *et al.* 2012; Cornelis *et al.* 2014; Vitorge *et al.* 2014). Fang *et al.* (2011) demonstrated that TiO₂-NPs could act as a metal carrier and facilitate for instance the mobilization of metals, such as copper, in soil. These results raise concerns about the potential environmental risk associated with increased migration rates of co-contaminants and increased bioavailability of some toxic metals in the presence of NPs (Chekli *et al.* 2016; Fang *et al.* 2016). Because of the interactions between these multiple environmental factors in natural soils, it is difficult to predict the fate of NPs in soil based on investigations conducted in simple and poorly reactive porous media. In particular, it remains very difficult to hierarchize the dominant factors controlling the transfer of manufactured nanoparticles in natural soils, since most of these factors are closely related in such media. Studies evaluating the simultaneous effects of several soil factors on NPs mobility are clearly needed to elucidate the key soil properties that control NPs transport.

The objective of this study is to determine the influence of soil texture and OM content on the transport of two relevant manufactured nanoparticles, CuO-NPs and TiO₂-NPs in contrasted soils. We conducted water-saturated column experiments with six agricultural soils with contrasted physicochemical properties. For this, we implemented 3 different soil textures: from sandy to clayey soils, and two OM contents for each soil texture. The measured NP breakthrough curves were fitted with the Convection Dispersion Equation (CDE) to identify the dominant processes involved in the transfer of these two NPs in the soils and to quantify the corresponding parameters.

Material and methods

Soils

This study was conducted with soils belonging to three different textural classes: sandy-loam,

loam and silty-clay. Soils were collected from the upper 20 cm layer of three different agricultural sites located in the Rhône-Alpes and Burgundy regions of France (see Simonin *et al.*, 2015 for further details). At each site, the sampling was performed in two plots with low and high OM contents distant of less than 500 m. Therefore, the experiments were performed with six test soils with three different textures and two different OM contents for each texture. After collection, visible rocks, roots and plant litter of poor reactivity were manually removed. The soils were sieved (2 mm) and homogenized before storage at 4°C. These soils were previously characterized (Simonin *et al.* 2015) and some soil physicochemical properties are presented in Table 1.

Soil solutions from the six soils were prepared following the protocol described by Simonin *et al.*, (2015) and used as background leaching solutions in the column breakthrough experiments. Briefly, soil solutions were prepared by agitating 10 g of fresh soil dispersed in 50 mL of ultrapure water during 30 minutes at 180 rpm and 20°C in a refrigerated incubator shaker (New Brunswick - Eppendorf, Hamburg, Germany). The solutions were then centrifuged for 20 min at 8000 g, 20°C (Centrifuge 5804R, Eppendorf, Hamburg, Germany) to eliminate particles larger than 20 nm according to the Stokes' law. The supernatants were collected and stored at 4°C before characterization (Table 2) and used for NPs suspensions preparation (dispersion by vortexing the suspension 2 min. at maximum speed) and application in column experiments. In these soil solutions, orthophosphate concentrations were determined by Ion chromatography (Metrohm 732/733 separation center).

Nanoparticles

TiO₂-NPs were provided in powder form by Sigma Aldrich (St Louis, USA) with crystal structure of anatase (80%) and rutile (20%) and 99.5% purity. These TiO₂-NPs presented a specific surface area of 35-65 m² g⁻¹ and a mean particle size of 21 nm as assessed by Transmission Electron Microscopy. CuO-NPs were also purchased from Sigma Aldrich in

110 powder form with a nominal size around 50 nm and a specific surface area of 23 m² g⁻¹,
111 according to the manufacturer's information. Both NPs were used as bare NPs without any
112 coating and were characterized for intrinsic primary particle size using a ZEISS Ultra 55
113 scanning electron microscopy – field emission gun (SEM-FEG). In average, TiO₂-NPs
114 measured 28.7 ± 7.1 nm and CuO-NPs measured 57.0 ± 18 nm.

115 The apparent hydrodynamic diameter and zeta potential of the NPs were characterized using
116 Dynamic Light Scattering (DLS) with a NanoZS (Malvern) directly in the soil solutions.

117 The measurements were performed in triplicate after dispersion through ultrasonication for 5
118 min in the spiking suspensions of NPs prepared at 50 mg L⁻¹ in soil solutions.

119 **Column experiments**

120 The soil solutions were used as background leaching solutions for the duplicated column
121 experiments. Spiking suspensions of NPs at 50 mg L⁻¹ were prepared and injected in columns
122 only after ultrasonication for 5 min. This NPs concentration is in the lower range of
123 concentrations found in literature for similar transport studies in natural soils (e.g. Cornelis *et*
124 *al.* 2014). The transport experiments were performed in small glass columns (C10/10, GE
125 Healthcare) of 1 cm in diameter and 10 cm long, homogeneously packed with 8 cm of wet soil
126 as described by Martins and Mermoud (1999), corresponding to approximately 8 g of dry soil.
127 Flow adaptors (AC 10, GE Healthcare) were adjusted on the top of the columns to ensure a
128 constant soil height during experiments. Soil bulk density values are presented in Table 3, along
129 with the values of porosity and volume of pore water. At the beginning of the experiments, soil
130 columns were saturated and leached from bottom to top with 100 mL of freshly prepared soil
131 solution. The effluents were collected using a fraction collector (Gilson 203A) to check for the
132 turbidity of the outflow by measuring the absorbance at 600 nm (Spectrometer Biowave II,
133 Biochrom WPA). The absorbance was very low for all soils (< 0.02), indicating that the amount

134 of soil colloids in the effluents was negligible. Bromide (Br) ion was used as water tracer to
135 assess the hydrodynamic properties of the soils before NPs injection. About two pore volumes
136 of bromide tracer (KBr 1 g L⁻¹ also prepared in soil solution) were injected in each soil column
137 and followed by 2 pore volumes injection of bromide-free soil solution. The concentrations of
138 Br⁻ in the soil column effluents were measured by Ion chromatography (Metrohm 732/733
139 separation center) with a detection limit of 4 µg L⁻¹.

140 The spiking suspensions of NPs (TiO₂ or CuO) prepared at 50 mg L⁻¹ (C₀) in soil solution were
141 injected in the columns at a flow rate of 0.1 mL min⁻¹ during around 4 to 6 pore volumes. After
142 NPs spiking, the columns were continuously leached with soil solution for at least 15 pore
143 volumes. The column effluents were sampled in 15 mL centrifuge tubes every 10 minutes (~1
144 mL collected). Total concentrations of titanium (Ti) or copper (Cu) were measured in the
145 spiking suspensions (C₀) and in the effluents (C). The breakthrough curves of NPs are presented
146 in a dimensionless form: C/C₀ as a function of V/V₀, the dimensionless eluted volume, with V
147 normalized by V₀, the total pore water volume in the saturated column. All column experiments
148 were performed in duplicate.

149 Metal concentration analyses were performed using microwave-assisted (Novawave, SCP
150 Science) strong acid extraction (for Ti: hydrofluoric acid + nitric acid and for Cu: *aqua regia*).
151 Cu and Ti concentrations were determined using inductively coupled plasma optical emission
152 spectrophotometer (ICP-OES; Varian 700-ES, Varian Inc. Scientific Instruments, Palo Alto,
153 USA). With this methodology, Ti and Cu concentrations measured in a certified soil reference
154 material (sandy loam 10, RTC-CRM027, lot HC027, Sigma-Aldrich) were in good agreement
155 with certified values (95–102%). The detection limit was 50 µg L⁻¹ for both Cu and Ti
156 measurements. For each soil, breakthrough experiments were performed in control columns by
157 injecting only soil solutions without NPs to determine the background concentration of Ti and
158 Cu in the effluents. This background concentration was then subtracted from the measured

concentrations of Ti and Cu in the effluents. The main characteristics of the soil columns are provided in Table 3.

Determining concentration profiles of Ti and Cu along the soil columns after NPs breakthrough was an important objective of the work. However, the soils used contain naturally relatively high background concentrations of Ti and Cu (measured at 2400-5300 mg kg⁻¹ and 10-26 mg kg⁻¹, respectively, Table 1). For Ti, the injected amount of ~ 175 µg by soil column represents about 0.3-0.7% of the natural background Ti concentration present in the column. For Cu, the same injected quantity is close to the soil Cu background concentration. Consequently, as already reported (Nickel et al. (2015) who used concentrations several orders of magnitude higher than in this study (5 g/L), due to solid Ti and Cu contents in these and in other soils, it is not possible to quantify the metals sorbed from the spiking solution, when using environmentally relevant NP concentrations, at least without specific NPs labeling (Vitorge *et al.* 2013), which was indeed not the case in this work.

To evaluate the occurrence of CuO dissolution in spiking suspensions during each column experiment, a dissolution test was performed. The six NPs spiking suspensions (one for each soil) were prepared and sampled (5 mL) after 6 hours corresponding to the maximum duration of the NPs column transport experiments. Dissolved Cu concentration in samples were determined by ICP-OES (Varian 700-ES) after centrifugation for 20 min at 6000 g in a 5 kDa ultrafiltration device (Vivaspin tube, Sartorius). Soil solutions without CuO-NPs were used as controls. The dissolution of TiO₂-NPs in spiking suspensions was not assessed because these NPs are not soluble in water (Chen and Mao 2007; Duester *et al.* 2011).

Transport parameters estimation

The CXTFIT code implemented in the STANMOD software (USDA) (Toride *et al.* 1995) was

used to fit the tracer and NPs breakthrough curves. The pore water velocity (v , cm h^{-1}) and dispersion (D , $\text{cm}^2 \text{s}^{-1}$) in the NPs transport simulations were determined from the bromide tracer breakthrough curves obtained in the same soil. The analytic solution of the Convection Dispersion Equation (CDE) with a first-order loss term, μ , presented in Eq.1 was fitted to the bromide and NPs breakthrough curves using the Levenberg Maquardt algorithm (e.g. Martins and Mermoud 1999 ; Martins *et al.* 2013; Vitorge *et al.* 2013; Lakshmanan *et al.* 2015).

$$R \frac{\partial C}{\partial t} = D \frac{\partial^2 C}{\partial z^2} - v \frac{\partial C}{\partial z} - \mu C \quad \text{Eq.1}$$

where C is the NPs or tracer concentration, R is the retardation factor (dimensionless) of NPs (ratio of NPs and tracer residence times in soil columns), t is time, z is the distance from the inlet, v is the average pore water velocity calculated by dividing the water flow by the column section and the soil volumetric water content, D is the soil dispersion coefficient and μ is the NPs decay coefficient, related to their irreversible retention on solid collectors (soil constituents). For bromide experiments, only v , R and D parameters were calculated. For NPs experiments the parameters v , R , D and μ were calculated for the fitting of the breakthrough curves, using the values determined for the tracer as initial fitting values.

Characterization of soil organic matter by infrared spectroscopy

To evaluate the differences in organic matter quality between the 6 soils in relation to soil interactions with CuO-NPs, both soils samples and soils solutions were analyzed by MIR-ATR spectroscopy. Prior to infrared soil spectra acquisition, the six soil samples were prepared as follows: soils were air-dried for 10 days after dry sieving at 2 mm. The fine soil fraction was then finely ground (0.25 mm) using an ultra-centrifugal mill (ZM 200, Retsch) and further dried over-night at 40 °C without altering soil organic matter. MIR measurements were performed

using Fourier-transform diamond attenuated total reflectance (MIR-ATR) on ca. 50 mg aliquots with an iS10 spectrometer (Thermo Scientific). MIR-ATR spectra were obtained after correction for interferences by H₂O and CO₂, by averaging 16 scans per sample at a 4 cm⁻¹ resolution over the spectral range [4000–400 cm⁻¹]. MIR-ATR measurements of the six soil solutions were performed using Fourier-transform diffuse reflectance on 50 µL (1 drop) with the same equipment from Thermo Scientific. Deionized water was used as background solution. The ATR spectrum of water was automatically deduced from the samples spectra for normalization.

Statistical analysis

The results of NPs hydrodynamic diameter, zeta potential and dissolution in soil solutions are presented as means (± standard errors) of 3 replicates. The influence of soil texture and OM content on NPs hydrodynamic diameter and zeta potential was investigated with a two-way Anova using the R software.

Results and discussion

Physicochemical properties of nanoparticles in soil solutions

Apparent size

CuO and TiO₂-NPs were characterized in the six soil solutions used for preparing the spiking suspensions in the transport experiments (Figure 1). The values of hydrodynamic diameter of TiO₂-NPs ranged from 73.9 to 128.1 nm, which is 2.7 to 4.6 times their intrinsic size of 28.7 ± 7.1 nm measured by SEM.

The content of solid OM in soil appears to only weakly affect the hydrodynamic parameters of NPs (Figure 1A): A marked difference is noted only for the Silty-Clay soil (Figure 1A). The difference relates probably more to the contrasted DOC and Ca content in these two soils (Table 2). DOC is known to facilitate colloids dispersion and stabilization (French *et al.* 2009; Badawy *et al.* 2010; Simonin *et al.* 2015; Qiu *et al.* 2020) whereas Ca is known to complex and neutralize, i.e. to precipitate DOC. Coherently, the soil of lowest DOC is that of highest Ca content (the high OM silty-clay soil, Table 2) and the NP's hydrodynamic diameter differs significantly from its sister soil (Low OM silty-clay soil). DOC thus appears to affect the hydrodynamic parameters of NPs more than soil texture.

In comparison, the CuO-NPs hydrodynamic diameter values of 53.3 to 84.1 nm are lower than those of TiO₂-NPs. These values measured in the soil solutions were close to the intrinsic value of 57 ± 18 nm measured by SEM. No significant influence of soil texture or OM content on CuO-NPs aggregation was observed (Figure 1B). These results evidence that CuO-NPs are less aggregated than TiO₂-NPs in all soil solutions, except in that of the loam soil with high OM (Figure 1B). The point of zero net proton charge (PZNPC) of Rutile and Anatase is 5.3 and 5.4 (Machesky *et al.*, 1994; Kosmulski, 2002), so TiO₂-NPs are negatively charged at circumneutral pH in pure water (Simonin *et al.*, 2015). On the other hand, the PZNPC of native CuO-NPs is equal to 10, they are therefore positively charged in pure water at circumneutral pH. Supposedly the association of the CuO NP's with soil DOM decreases their charge down to negative values, favoring their stabilization. Such a charge inversion effect was observed for CuO NP – humic acid suspensions (Sousa and Teixeira 2013). Possibly, this charge relationship explains the observed higher stability of CuO NPs versus TiO₂-NPs.

Zeta potential

Both TiO₂ and CuO-NPs presented negative zeta potentials in all soil solutions (Figure 1C and 1D). The zeta potential of TiO₂-NPs ranged from -23.9 to -15.5 mV whereas that of the CuO-

NPs ranged between -20.8 nm and -13.8 mV. For CuO-NPs in contact with Aldrich humic acids, similar negative zeta potentials were observed at similar pH and ionic strength (Sousa and Teixeira, 2013). This comparison suggests that dissolved OM and Aldrich humic acids have similar effects on NPs zeta potential. This result is conceptually in agreement with recent findings, which show that humic acids are constituted as loosely bound molecules of relatively small size, which compare to DOM in terms of composition and acid-base reactivity and consequently charge density (Hruška *et al.* 2003; Sutton and Sposito 2005; Causse *et al.* 2013). The zeta potential of CuO-NPs in soil solutions with high OM content were consistently more negative than in solutions of low OM content, while the observation is reverse for TiO₂-NPs. This surprising behavior is probably related to the high affinity of Cu for OM (Jacobson *et al.* 2007; Morel *et al.* 2014; Navel and Martins 2014), which can result in a greater OM coating effect on CuO-NPs compared to TiO₂-NPs and consequently decreased surface charge and zeta potential. Such effects are known to possibly lead to variable NPs surface charge in distinct soils (Simonin *et al.* 2015).

Hydrodynamic properties of the soils

The hydrodynamic properties of the six soils were determined by fitting the breakthrough curves of the water tracer, the bromide ion, with the CXTFIT code (Figure 2A). The corresponding transport parameters are presented in Table 4 with those adjusted for the CuO-NPs and TiO₂-NPs. All bromide breakthrough curves presented mass recoveries close to 100%, as expected with an inert water tracer. Retardation factors (R) of bromide were all close to 1, except that calculated in the silty-clay- high OM soil. In this soil, R was 0.81, which indicates that some of the pore water was not traced by the water tracer, probably in relation with the high clay content of this soil and/or ionic exclusion or poorly accessible immobile water (Monrozier *et al.* 1993). Dispersion values (D) fitted to the breakthrough curves are quite low

(below $10^{-7} \text{ cm}^2 \text{ s}^{-1}$) and almost similar for all soils. These parameter values were used as initial D values in CXTFIT to fit the breakthrough curves of the NPs in the corresponding soils.

Transport of TiO₂-NPs in soil columns

The mobility of TiO₂-NPs was found to be very low in all soils, with mass recoveries ranging between 1.9 and 5.5% (Table 4). These NPs breakthrough curves measured in the six soils were very noisy, indicating that the measured Ti concentrations were in the range of Ti background concentration in the leachates (Figure 2B). Consequently, transport modelling was not possible for the TiO₂-NPs breakthrough curves. In all soils the irreversible retention of TiO₂-NPs was higher than CuO-NPs. This strong retention probably relates to the observed higher homoaggregation of TiO₂-NPs in soil solutions, which increased the apparent NPs' size by a factor of 2.5 to 4.5 (Figure 1) in agreement with Vitorge *et al.* (2013). No clear influence of the soil OM content on TiO₂-NPs mobility could be evidenced in the six soils, because of their very low mobility. These results contrast with previous studies on the mobility of TiO₂-NPs conducted in columns of glass beads or sand material, which usually present these NPs as mobile especially at alkaline pH (Ben-Moshe, Dror and Berkowitz 2010; Solovitch *et al.* 2010; Chowdhury, Cwiertny and Walker 2012; Rastghalam *et al.* 2019). However, our results are consistent with previous works conducted in natural soils by Wang *et al.* (2014) or Nickel *et al.* (2015), although these experiments were performed with positively charged TiO₂-NPs. A study performed in natural soils is in significant disagreement with strong retention of TiO₂ NPs (Fang *et al.* 2009). They used negatively charged TiO₂-NPs as in our study but observed a significant transport of these NPs, especially in soils with low clay, high DOM content and low ionic strength. Their DOC values are all much higher than those of our study (factor ~ 7), which could indicate a dominant effect of this factor on NPs mobility, especially considering their rather similar or even decreased Ca^{++} values. In this study, NPs are transferred as a tracer

especially at high DOM content. Fang et al., (2016) observed a similar behavior of TiO₂ NPs in the presence of fulvic acids. Since in our experiments, the retention of TiO₂-NPs was very high in the six soils studied, it was not possible to observe any influence of the soil texture (soil clay content) or of the ionic strength of soil solution. In our six soils, TiO₂-NPs were not transported deeper than 8 cm. This result may relate to the relatively low DOM content of the soils, low NPs input concentration and/or other parameters such as soil aggregation column size and setup. Studying the fate of TiO₂-NPs in soil is very challenging as Ti is abundant in soils and presents a very heterogeneous distribution. The findings obtained with laboratory saturated soil columns give a first assessment of the risk of NPs migration to deeper soil layers or groundwater, which appears very low. However, further work is clearly needed to assess the mobility potential of TiO₂-NPs at environmentally relevant concentrations, in undisturbed soils or under unsaturated conditions and simulating repeated exposures in order to be closer to expected field conditions (Duester *et al.* 2011; Cornelis *et al.* 2014; Conway and Keller 2016; Simonin *et al.* 2016).

Chemical stability and transport of CuO-NPs in soil columns

In order to calculate accurate mass balances for the column NPs-displacement experiments, the ability of CuO-NPs to dissolve in the six soils solutions was first assessed in the spiking suspensions through a 6-hour kinetic study. CuO-NPs dissolution was found to be negligible in all soil solutions, ranging from 0.22 and 0.49 % of the NPs applied mass (50 mg/L), after 6 hours of contact, which represents the maximum residence time of the NPs in the columns during transport experiments (Table 2). The measured aqueous Cu concentrations ranged from 0.112 to 0.243 mg L⁻¹ that situate all below the PHREEQC-calculated Cu solubility limits toward Tenorite (Parkhurst and Appelo 2013). This evidences a slow dissolution kinetic of the NPs. Consequently, Cu concentrations measured in the effluents can be attributed to CuO-NPs

and not to dissolved Cu species.

All CuO-NPs breakthrough curves were fitted with the Convection Dispersion Equation, using the hydrodynamic parameters determined with the water tracer. The observed and CDE-Fitted breakthrough curves of CuO-NPs are presented in Figure 2A together with those of the water tracer (Br). The corresponding parameters are presented in Table 4. The CuO-NPs breakthrough curves (Figure 2A) show that these NPs are only partially mobile in the six soils, as important amounts of NPs were irreversibly retained in all soils, with NPs mass recoveries ranging from 5.2 to 14% (Table 4). Unlike TiO₂-NPs, the partial mobility of CuO-NPs provided breakthrough curves that can be used to assess the influence of the studied factors on the transport of CuO-NPs. In all soils, the eluted CuO-NPs presented a fast transport through soil columns with no or low retardation as compared to the bromide tracer (Table 4). No clear effect of soil texture could be observed with the tested soils and, in particular, CuO-NPs were not specifically more mobile in the sandy-loam soils than in the loam or silty-clay soils as commonly observed for other types of pollutants (pesticides, PAH, heavy metals...) and as expected from previous work (Fang *et al.* 2009). In the sandy-loam soils, CuO-NPs were transported slightly faster than the tracer ($R = 0.98$ and 0.91) indicating that in this type of soil, the NPs do not “see” all the water present in the soil presumably due to size exclusion processes or exclusion from immobile water zone during their transport (Table 4). In the loam and silty-clay soils, the CuO-NPs were transported slightly slower than water and presented a retardation factor slightly higher than 1, especially in the low OM soils. As for the tracer, the retardation factor measured in the high OM soils appeared always lower than in the low OM soils, indicating a clear relation between NPs mobility and soil OM content. This is possibly related to an increased soil structuration induced by the higher OM content in soil compared to the low OM soils (Jastrow 1996; Álvaro-Fuentes *et al.* 2009). Such soil structuration improvement is indeed known to increase soil permeability through the formation of slightly bigger pores, which can facilitate the transfer of

colloids or bacteria (Martins *et al.* 2013; Vitorge *et al.* 2013; Bagheri *et al.* 2019). Under our conditions, the different apparent size and zeta potential values of CuO-NPs measured in the different soil solutions do not seem to significantly affect NPs mobility whatever the soil. In the two loam soils of low and high OM contents, the CuO-NPs breakthrough curves were indeed very similar (Figure 2A), although their zeta potential values were the most contrasted (Figure 1), indicating that electrostatic interactions are probably not the dominant NPs retention process in the tested soils.

While in loam soils the NPs breakthrough curves were very similar in both low and high OM content conditions, in the sandy-loam and silty-clay soils, the breakthrough curves varied oppositely between the high and low OM condition (Figure 2). Interestingly, the mobility (recovery rate) of CuO-NPs increased by 62% in the high OM - sandy-loam soil compared to the low OM one, while in the silty-clay soil, CuO-NPs mobility decreased by 44% in the high OM soil compared to the low OM soil (Table 4, Figure 2A).

In the sandy-loam (high OM) and the silty-clay (low OM) soils, where CuO-NPs transport was enhanced, the concentration of dissolved organic carbon (DOC) in soil solutions was significantly higher than in the four other soils (Table 2). DOC concentration in soil solution appears thus as an important factor in NPs mobility, as has already been demonstrated in less complex porous media (e.g. Ben-Moshe *et al.* 2010; Rastghalam *et al.* 2019). Other factors are probably also involved in the higher mobility of CuO-NPs in these two soils (e.g., low Ca and Mg concentrations in soil solutions). Although several studies have evaluated the mobility of CuO-NPs in columns of glass beads or sand material (Ben-Moshe, Dror and Berkowitz 2010; Wu *et al.* 2020), this study is one of the first studies on the transport of CuO-NPs in a series of 6 agricultural soils. We have shown here that CuO-NPs are partly mobile in all the contrasted soils studied, although the majority (86 to 94.2%) of these NPs are retained in the 8 cm top layer of these soils.

380 **Spectral characteristics of soils and soils solutions**

381 To further assess the observed differences in the effects of solid and dissolved OM levels on
382 CuO-NPs mobility, a comparison of the MIR-ATR spectra of the six soils and of the six soil
383 solutions is presented in Figure 3. For the solid phase, all the MIR-ATR spectra are mainly
384 dominated by the strong absorption of soil minerals, which are very similar for the six soils.
385 Only slight insignificant spectral differences can be observed between the spectra obtained with
386 low and high OM soils (Figure 3A), which do not explain the observed differences in the
387 mobility of CuO-NPs. According to Stenberg *et al.* (2010) and Erktan *et al.* (2016), the most
388 frequent peaks in the MIR-ATR spectra of soils correspond to phyllosilicates (3622, 1635, 988,
389 and 795 cm^{-1}) and/or iron (oxy)hydroxydes (3622 and 795 cm^{-1}) and tannins (1612, 1450, and
390 669 cm^{-1}), with carboxylate (1592 and 1417 cm^{-1} , respectively), alkyl (CH_2 and CH_3 bending
391 vibrations at 1455 and 1380 cm^{-1} , respectively) and aromatic moieties (phenol O–H bend at
392 1370 cm^{-1}). The relatively low organic carbon content (a few %) of soils (Table 1) may explain
393 the dominant absorption of soil minerals in mid-infrared.

394 For soils solutions (Figure 3B), although the MIR spectra appear very similar, slight differences
395 can be observed in the 1200-980 cm^{-1} IR range of interest (black rectangles). Although
396 incomplete correction of the background atmosphere (CO_2) could have occurred, this is
397 particularly visible in the wavelength ranges relating to dissolved inorganic phosphorus
398 species(e.g. Tammer 2004; Elzinga and Sparks 2007; Klein *et al.* 2019). In this range, slightly
399 higher or lower absorptions, corresponding to different Phosphate species were observed for
400 the Sandy-Loam (high OM) and Silty-Clay (low OM) soil solutions, which are precisely the
401 soils in which the mobility of CuO-NPs was highest (Figure 2). On the contrary, MIR
402 absorption was lowest or highest in this range for the Sandy-Loam (low OM) and Silty-Clay
403 (high OM) in which CuO-NPs mobility was lowest. In the 980 to 1200 cm^{-1} range, IR absorption

was very similar for the solutions of the two loam soils, in which CuO-NPs transport was very similar. For the sandy-Loam (high OM) and silty-Clay (low OM) soils, chemical analysis of P in soil solutions (Table 2) is in agreement with these IR trends and confirms the presence of higher concentrations of dissolved phosphate in the soils in which CuO-NPs are the more mobile. These results clearly suggest the existence of interactions between CuO-NPs and dissolved phosphorous (P) species in the soils that could explain the better stability of NPs in solution and therefore their slightly higher mobility in soils.

Phosphate effect on NPs transport

Phosphate is known to strongly sorb on metal oxides (e.g. Fe, Cu and Al oxides) even in acidic natural environments (Mahdavi and Akhzari 2016; Claudio *et al.* 2017; Klein *et al.* 2019). These properties have been used for various purposes, such as in agronomy to enhance phosphorus phytoavailability in soil (Zahra *et al.* 2015) or in wastewater treatment to eliminate phosphorus species (Acelas *et al.* 2015).

Our data suggest that phosphate species increase the mobility of CuO-NPs in the soils studied. Several studies performed in quartz sand columns suggested a similar positive influence of phosphorus species on several types of NPs and especially of TiO₂-NPs (Hou *et al.* 2017; Rastghalam *et al.* 2018; Xu *et al.* 2020). Xu *et al.* (2018) studying a TiO₂ NP's - phosphate - bacteria ternary system showed that phosphate species generally facilitates the transport of TiO₂ NPs linked on bacteria except in the presence of Fe oxide coatings or of low phosphate concentrations.

The main effect of phosphate appears to be the decrease of NPs surface charge induced by phosphate sorption. The stronger negative zeta potential of NPs probably results in enhanced repulsion of similarly charged soil constituents and, consequently, in the better stability and facilitated transfer of NPs in soil. In addition, the high complexing capacity of P may enable

the formation of ternary complexes and, consequently, bridges between positively charged moieties, which are relevant for soils (Sheng *et al.* 2019; Mendez and Hiemstra 2020). Zhara *et al.* (2015) suggested that positively charged TiO₂-NPs, are destabilized by inter-particle phosphate bridges. Concerning Xu *et al.* (2018), supposedly phosphate species bridge NPs to positively charged Fe oxide surfaces, as long as sorbed phosphate does not inverse the Fe oxide surface charge.

Globally, the effect of phosphate on NPs appears to be diverse. A facilitation of transport and dispersion effect linked to the negative charge of the sorbed phosphate species is potentially associated with an opposite immobilizing and aggregation effect linked to phosphate ternary bridging. Based on our observations, this study suggests that the apparent charge effect appears to be the dominant process under our conditions.

In conclusion, this study demonstrated a low or very low mobility of CuO and TiO₂-NPs in agricultural soils, respectively. When differences in NP mobility were observed between soils, they seemed to be mainly due to dissolved OC and phosphate concentrations in soil solution. Globally, the low mobility of NPs observed in an 8 cm soil layer in this study suggests that these two NPs present a low risk of direct groundwater contamination in a wide range of surface soils, although mobilization mechanism effects, probably involving P species, could increase this mobility and thus the associated risk for water supply. This low mobility also raises concerns about the long-term impacts of NPs on plants and soil biodiversity in agroecosystems that would require to be investigated under realistic field conditions.

Acknowledgments

Marie Simonin was supported by a Ph.D grant from Rhône-Alpes Region – ARC

Environnement. This work was funded by a grant from the French National Program Microbien EC2CO-CNRS. The authors thank the lab assistance of Erwann Vince and Sophie Sebastianutti (MOME and AirOsol platforms at IGE) and also of Alix Dumay for modelling assistance. Special thanks are due to Lauric Cécillon and Alejandro Fernandez-Martinez for Infrared spectra measurements and help for interpretation. IGE is part of the Labex OSUG@2020 (ANR10 LABX56). We thank the Equipex NanoID (ANR-10-EQPX-39) for the access to the NanoZS (ISTerre).

B. MIR-DR spectra – Soil Solutions

692

693 Figure 3: A) MIR-ATR spectra of the 6 soils. B) MIR-DR spectra of the 6 soil solutions. Each
 694 spectrum corresponds to the average of 16 spectra. The vertical grey dotted lines show the
 695 position of distinguishable bands of interest as described in the main text: i) Vibrations between
 696 700 and 600 cm^{-1} are possibly associated to several elements (νCO_2 , $\nu \text{C-Cl}$, $\nu \text{C-Br}$, $\nu \text{PO} \dots$)
 697 due to incomplete correction of the background atmosphere, ii) Vibrations predominantly
 698 related to phosphate (e.g. νPO , νPO_2^- , νPO_3^{2-}) between 1120 cm^{-1} and 980 cm^{-1} .
