SUMMARY

Oryza sativa (rice) plays an essential food security role for more than half of the world’s population. Obtaining crops with high levels of disease resistance is a major challenge for breeders, especially today, given the urgent need for agriculture to be more sustainable. Plant resistance genes are mainly encoded by three large leucine-rich repeat (LRR)-containing receptor (LRR-CR) families: the LRR-receptor-like kinase (LRR-RLK), LRR-receptor-like protein (LRR-RLP) and nucleotide-binding LRR receptor (NLR). Using LRRPROFILER, a pipeline that we developed to annotate and classify these proteins, we compared three publicly available annotations of the rice Nipponbare reference genome. The extended discrepancies that we observed for LRR-CR gene models led us to perform an in-depth manual curation of their annotations while paying special attention to nonsense mutations. We then transferred this manually curated annotation to Kitaake, a cultivar that is closely related to Nipponbare, using an optimized strategy. Here, we discuss the breakthrough achieved by manual curation when comparing genomes and, in addition to ‘functional’ and ‘structural’ annotations, we propose that the community adopts this approach, which we call ‘comprehensive’ annotation. The resulting data are crucial for further studies on the natural variability and evolution of LRR-CR genes in order to promote their use in breeding future resilient varieties.

Keywords: LRR-receptor-like kinase, LRR-receptor-like protein, nucleotide-binding LRR receptor, annotation curation, pseudogenes, Oryza sativa, disease resistance gene.

INTRODUCTION

Modern agriculture is at a critical juncture, as the world’s population continues to grow but there is a call to shift away from chemical treatments to deal with current environmental issues. Crop pest and pathogen susceptibility is one of the main causes of annual crop yield loss (FAO, 2018; Savary et al., 2019). Despite an awareness of the harmful environmental impact, massive pesticide use remains a common means to prevent plant diseases today. Studying and understanding plant disease resistance and the underlying evolutionary mechanisms are of utmost importance to make effective widespread use of known sources of resistance through specific breeding programs, while also promoting new resistance engineering for crop sustainability (Bailey-Serres et al., 2019; Tamborski and Krasileva, 2020). The elucidation of resistance mechanisms in plants has highlighted a trove of resistance genes to combat the great and evolving genetic diversity of plant pathogens. The leucine-rich repeat (LRR)-containing receptors (LRR-CRs) are at the forefront of these genes. LRR-CRs share the common structural and functional LRR domain. This domain contains between two and 30+ repetitions of an approximately 24-amino-acid motif, characterized by a conserved skeleton composed mostly of leucine residues (Bella et al., 2008; Kajava, 1998; Kajava, 2012; Matsushima and Miyashita, 2012). These LRR-CRs are classified in three main gene families: LRR receptor-like kinase (LRR-RLK), also named LRR-RRK but referred to herein as LRR-RLK), LRR receptor-like protein (LRR-RLP) and nucleotide-binding-site LRR (NBS-LRR or NLR) (Han, 2019; Sekhwal et al., 2015) (Figure 1). The LRR-RLKs and LRR-RLPs are transmembrane receptors composed of an extracellular LRR domain and an intracellular domain. The intracellular domain is a kinase domain for LRR-RLK (Shiu and Bleecker, 2001a; Shiu and Bleecker, 2001b) and a short cytoplasmic tail for LRR-RLP (Fritz-Laylin et al., 2005; Jones

This is an open access article under the terms of the Creative Commons Attribution-NonCommercial License, which permits use, distribution and reproduction in any medium, provided the original work is properly cited and is not used for commercial purposes.
Some LRR-RLKs and LRR-RLPs play roles in intercellular communication involved in disease resistance (such as pattern-recognition receptors, PRRs), stress responses or developmental processes (Boutrot and Zipfel, 2017; van der Burgh and Joosten, 2019). Other LRR-RLKs and LRR-RLPs also act as co-receptors or regulators in these signaling pathways (Couto and Zipfel, 2016). NLRs are intracellular receptors composed of a central nucleotide-binding domain (NB-ARC domain) followed by the LRR domain (Burdett et al., 2019; Sekhwal et al., 2015; Tamborski and Krasileva, 2020; Xiong et al., 2020). These proteins can contain other functional domains, such as the Toll/interleukin receptor (TIR) domain, the coiled-coil (CC) domain or the resistance to powdery mildew 8 (RPW8) domain, located upstream of the NB-ARC domain. Over the past few decades, advances in sequencing have provided the research community with an ever-increasing number of complete genomes. These resources have made it possible to revisit gene evolution at the level of entire families and on different evolutionary timescales. LRR-CR genes have been inventoried in many angiosperm genomes, and their numbers have also been compared in a phylogenetic framework to shed light on their evolutionary dynamics (for just some of the more recent articles, see Andersen et al., 2020; Furumizu and Sawa, 2021; Hosseini et al., 2020; Lee et al., 2021; Man et al., 2020; Prigozhin and Krasileva, 2021). A large proportion of LRR-CR genes are thought to evolve through a so-called birth-and-death model (McDowell and Simon, 2006; Michelmore and Meyers, 1998; Nei and Rooney, 2005; Richter and Ronald, 2000). In this model, the gene copy number expands by recurrent duplication events and duplicated copies can then follow different evolutionary pathways, such as keeping the original function, acquiring a new function (neofunctionalization) or, more frequently, undergoing a non-functionalization process by accumulating nonsense mutations (Innan and Kondrashov, 2010; Leister, 2004). This model explains why LRR-CR genes are found in multiple copies, often organized in large gene clusters, with some genes no longer being functional (Meyers et al., 2003; Mizuno et al., 2020).

Comparative genomic studies have led to considerable progress in understanding the evolutionary dynamics of LRR-CR gene families, but these studies are highly dependent on the accuracy of annotation procedures. Given the increasing avalanche of sequence data, the most reasonable approach is to rely on automatic annotation. Gene and protein sequence annotation are thus crucial and the target of considerable effort. Structural gene annotation is geared towards identifying coding sequences within genomic data and documenting the associated gene features (e.g. introns, exons and untranslated regions, UTRs) (Wilming and Harrow, 2009). The most widely used structural annotation pipelines, such as the Ensembl pipeline for gene annotation (Aken et al., 2016), Augustus (Stanke and Waack, 2003) and Gnomon (https://www.ncbi.nlm.nih.gov/genome/annotation_euk/gnomon/), rely on: (i) *ab initio* gene structure determination according to rules learned on pre-existing annotations; and/or (ii) comparative approaches, i.e. using sequence homology with available RNAseq data and/or with a closely related annotated genome. Those methods allow large-scale studies with standardized approaches, yet they are not completely reliable, especially for complex multigene families. Indeed, repetitions are known to impair gene annotations (Bayer et al., 2018; Fawal et al., 2014) and there are also genome assembly issues (Torresen et al., 2019). The difficulty is twofold in the case of LRR-CRs: several similar genes are present in the genome as a result of gene duplication events, whereas each gene contains several similar motifs because of the repetitive structure of the LRR domain. The automatic annotation and classification of LRR-CRs is thus especially challenging. For example, although multiple studies have reported that there are more than 800 LRR-CR loci in the rice variety Nipponbare, the number of genes per family is variable, e.g. 374–498 NLR proteins (Li et al., 2010; Li et al., 2016; Shao et al., 2016; Stein et al., 2018; Zhou et al., 2004), 292–435 LRR-RLKs (Dufayard et al., 2017; Hwang et al., 2011; Man et al., 2020; Sun and Wang, 2011) and 90 LRR-RLPs (Fritz-Laylin et al., 2005). These variations are to a large extent linked to the annotation version chosen for the analysis and to the decision rules for gene detection and classification. Scientists sometimes perform the manual curation of gene annotations to limit these uncertainties and achieve high-quality comprehensive analyses, as in the case of Arabidopsis and Solanum lycopersicum (tomato) NLR genes (Jupe et al., 2013; Meyers et al., 2003; Van de Weyer et al., 2019) or Oryza sativa (rice) Nipponbare LRR-RLK genes (Sun and Wang, 2011).

Rice was the first monocotyledon plant to have its genome entirely sequenced and three different annotations of

Comprehensive annotation of rice LRR-CRs

Inconsistencies among three publicly available Nipponbare rice LRR-CR annotations

We used LRPRFILER, a newly developed pipeline (see Experimental procedures and Data S1, Methods S1, Figures S1 and S2 and Table S1 for LRPRFILER validation results, performed on a manually reviewed Arabidopsis thaliana protein data set and on the whole Arabidopsis proteome, including a comparison with the LRRPREDICTOR tool; Martin et al., 2020), to identify, annotate and classify into gene subfamilies the LRR-CR protein sequences of the three publicly available Nipponbare proteomes (MSU, IRGSP and NCBI). The total number of LRR-CRs identified varied markedly according to the annotation: we identified 1226 LRR-containing sequences in the MSU predicted proteome, 1047 in that of IRGSP and 1073 in that of NCBI (Table 1). The distribution patterns of these proteins in the different subfamilies also varied according to the annotations. For instance, the number of predicted genes fluctuated less for the LRR-RLP subfamily than for the NLR subfamily, for which 60% more NLRs were detected in the MSU proteome (418 proteins) compared with the IRGSP proteome (282 proteins). For comparison, we conducted a similar analysis on nine transcription factor (TF) subfamilies, for which we assumed that the annotation process would be easier as they had a more conserved structure and, although having undergone expansion events, were not evolving under a birth-and-death model (Lai et al., 2020). The TF data set contained between 874 and 1041 genes, according to the annotations, and this number was similar to that of LRR-CR. To assess whether the identified genes were at the same genomic location or not, we measured the overlap of the three predicted gene sets. The percentage of loci for which a gene model was present in all three annotations was 52.3% for LRR-CR genes and 69.5% for TF (Figure 2a), indicating that the three annotations were more congruent for TF genes. Moreover, the percentage of loci in which only one annotation detected a gene was 19.5% for LRR-CR genes, compared with only 12% for TF genes.

Even when a gene was predicted by the different annotations, the predicted structure of the gene sometimes varied between predictions. One way to address this issue is to compare the length of the predicted proteins for genes positioned at the same locus. Note that this is a conservative approach. Indeed, although a predicted protein length difference between two gene models indicated that the gene models differed, the reverse was not true, as identical forms can be predicted by different models.

predicted protein lengths did not guarantee that the gene models were identical. A comparison of predicted protein lengths for all LRR-CR gene pairs located at the same locus but predicted by two different annotations is presented in Figure 2b and Figure S3. Here, again, the number of genes with a difference in the predicted protein length highlighted a substantial annotation discrepancy. This difference was greater for LRR-CR genes than for TF genes. As an example, when IRGSP and MSU were compared, the average difference between the predicted product sizes was 18.7% for LRR-CR loci (with an $R^2$ of only 0.42), whereas this difference was only 8.6% for TF loci (with a much higher $R^2$ of 0.77) (Figure 2b). These results highlight the extent to which annotations generally differ, but more particularly for LRR-CR gene subfamilies. These comparisons also showed that LRR-CR genes predicted by IRGSP were generally shorter than those predicted by MSU or NCBI at the same locus (Figure 2b and Figure S3).

**Manual re-annotation of LRR-CR-encoding loci in the Nipponbare rice genome**

Here we provide a brief description of the procedure that we followed to manually curate LRR-CR annotations (Figure 3a). First, note that for the sake of traceability the procedure retained one of the three proposed gene models as much as possible. For a given locus, we first selected one of the gene models among the available annotations based on the completeness of the predicted protein. We then applied our expertise to the selected gene model by combining protein and nucleotide data. At the protein level, we checked that all of the expected domains for each subfamily were present (e.g. LRR and TM for LRR-RLPs and LRR-RLKs, kinase for LRR-RLKs or NB-ARC for NLRs) in the right order, with the expected length and interdomain intervals. Protein domain information was particularly useful for detecting potential gene fusion and fission. At the nucleotide level, we examined: (i) whether the gene models had the expected intron/exon structure (e.g. introns, when present, are often found at the same exact position); (ii) whether nearby open reading frames (ORFs) belonging to LRR-CR-encoding sequences were present; and (iii) whether the gene models included suspicious introns, such as short introns, enabling the gene to sidestep stop codons or frameshifts, especially when they were never found in homologs (Figure 3b). Any structural annotation containing an in-frame stop codon or a frameshift (i.e. any gap in coding sequence that was not an intron but that changed the translation phase), lacking a start codon or a terminal stop codon, or presenting an unexpected splicing site (different from the GT-AG and GC-AG donor/acceptor canonical splicing sites) was called ‘non-canonical’. This careful inspection was facilitated by viewing the sequence annotations with the ARTEMIS editor (Carver et al., 2012).

In a last step, we also looked for LRR-containing sequences that would have been missed by the three publicly available annotations. The Nipponbare reference genome was split into 1-kb segments with overlapping 100-bp borders, translated into amino acid sequences in the six reading frames (as performed by Steuernagel et al., 2020), and domains (LRR, kinase, NB-ARC, etc.) were searched.
with HMMSEARCH. All the results were concatenated and filtered for redundancies. The retained new sequences of interest had to contain at least three LRR motifs in tandem. If another domain was detected at less than 5 kb from these LRR motifs, the sequence of interest was enlarged to also include these domains. These sequences, not overlapping known LRR-CR exons, were compared with other plant genomes using BLAST to screen for the potential presence of a gene model in the region under consideration.

The final set of manually validated LRR-CR loci on the Nipponbare genome consisted of 1058 genes (350 LRR-RLKs, 147 LRR-RLPs, 503 NLRs and 58 UCs) (Data S2; Table 2). Among these 1058 genes, eight (one LRR-RLK, three LRR-RLP and four UC) were located at loci for which none of the three publicly available annotations detected a gene. The LRR-RLK was a canonical full-length sequence on the forward strand of chromosome 2 (from 6 831 702 to 6 834 761). Note that this sequence is actually present in GenBank under accession number EAZ22278.1 and is located on the reverse strand in a non-coding region of the Os02g0222500 gene. The other seven are non-canonical truncated genes. In addition, for seven of these 1058

| Numbers in parentheses are newly identified LRR-CR genes. Percentages were calculated based on the number of manually curated genes, i.e. the total number of genes minus the number of newly identified genes.

LRR-CR proteins derived from the reference annotations to the number of functional domains found in the proteins derived from our expert annotation (Figure S4). These comparisons revealed that quite a few more LRR-CR domains were found in our manual annotation as compared with the publically available annotations. For example, when compared with the reference IRGSP annotation, our expert annotation highlighted 29% more TM, 42% more NB-ARC, 33% more kinase and 20% more LRR motifs.

Annotation of the LRR-CR genes in the rice cultivar Kitaake

Kitaake is another O. sativa ssp. japonica variety for which a complete genomic sequence is available (Jain et al., 2019). In order to compare the LRR-CR repertoire between Nipponbare and Kitaake and limit the need for manual curation in the re-annotation of this closely related rice cultivar, we developed a strategy to transfer our expert annotations from the Nipponbare to the Kitaake genome.

The strategy summarized in Figure 4 starts by identifying Kitaake genome regions that are homologous to Nipponbare LRR-CR sequences. Then it successively takes into account three levels of annotation transfer, depending mostly on the level of sequence identity of each considered region with the LRR-CR gene that identified it. At each locus, our strategy strives to retrieve the most probable gene model with the idea that, if possible, it should be canonical. At the end of the process, LRR-CR gene models that are found to be non-canonical or having a dubious protein structure in Kitaake are manually checked and corrected if needed. At this step, the transfer allowed us to identify 1046 LRR-CR genes in the Kitaake genome.

As carried out for Nipponbare, the Kitaake genome was finally scanned with LRR HMM profiles using HMMSEARCH for new LRR-CR identifications. This procedure allowed us to annotate 18 additional genes, thereby leading to a total of 1064 LRR-CR genes in the Kitaake genome.

One way to assess the relevance of our expert LRR-CR annotation is to compare the number of functional domains (TM, NB-ARC, kinase and LRR) found in validated genes, the LRRPROFILER pipeline did not detect any further LRR motifs in the predicted protein. LRR motifs were initially detected for these genes, but at the threshold limit when using HMM profiles built on the basis of the initial data set (for details, see the LRRPROFILER pipeline section in the Experimental procedures). When using the slightly different HMM profiles obtained with the final data set, the same LRR motifs were no longer detected as they did not surpass the threshold. However, a careful manual inspection showed that the LRR domain was present but contained divergent LRR motifs, thereby complicating the automatic detection. Consequently, these genes were kept and classified according to the presence of the other domains (kinase or NB-ARC). These seven genes included one LRR-RLK and six NLRs.

Among these 1058 LRR-CR genes, 328 (197 NLR, 56 LRR-RLK, 55 LRR-RLP and 20 UC) were manually modified because none of the three publicly available annotations had a satisfactory gene model based on the previously defined criteria (Data S2; Figure 3a). The overall proportion of modified loci was 31.0% (328/1058), and varied markedly according to the gene subfamily concerned. Only 16% of LRR-RLK loci were modified, whereas 37.4% of the LRR-RLP loci and 39.2% of the NLR loci were modified (Table 2). Among these 1058 LRR-CR genes, 306 (28.9%) were non-canonical. Again, the different gene subfamilies did not contain the same proportion of non-canonical gene models. Very similar to what was observed regarding the proportion of modified gene models according to gene subfamily, non-canonical gene models concerned only 15.1% of the LRR-RLKs, compared with 32.7 and 36.4% of the LRR-RLPs and NLRs, respectively. Thus, 274 genes were both non-canonical and modified, representing 83.5% of the total modified loci (274 over 328) and 89.5% of the non-canonical loci (274 over 306) (Table S2). The remaining 32 non-canonical genes were either unreported by any of the annotations (seven) or were reported by the NCBI as pseudogene or gene models having putative errors in the genomic sequence (25, see below).

at this step, manual validation of the protein annotations confirmed the presence of an LRR domain of the expected size and located at the expected positions. These 11 genes were therefore kept in the final data set. The gene subfamilies for these 11 loci were determined based on other functional domains and a homology search against other LRR-CR protein sequences. Finally, the LRR-CR gene set from Kitaake was composed of 360 LRR-RLKs, 140 LRR-RLPs, 510 NLRs and 54 UCs (Data S3; Figure 5). These numbers were very similar to those obtained for Nipponbare, i.e. 350 LRR-RLKs, 147 LRR-RLPs, 503 NLRs and 58 UCs.

We then tagged all of these Kitaake LRR-CR gene models as either canonical or non-canonical. We obtained 742 (69.7%) canonical genes and 322 (30.3%) non-canonical genes. Again, the proportions of canonical and non-canonical genes per subfamily for Kitaake were very similar to those obtained for Nipponbare (Figure 5).

A notable result is that our strategy enabled us to identify 114 LRR-CR genes (48 of which were canonical) that were not present in the publicly available annotation of the Kitaake genome: 17 LRR-RLKs, 24 LRR-RLPs, 50 NLRs and 23 UCs.

The comprehensive annotation of rice LRR-CRs can be viewed and downloaded on the dedicated website (https://rice-genome-hub.southgreen.fr/content/geloc).

Comparison of LRR-CR allelic pairs between Nipponbare and Kitaake

Nipponbare and Kitaake are two varieties of the same subspecies: O. sativa ssp. japonica. As such, for the majority of the genes found in Nipponbare, an allele (i.e. a version of the same gene located at the same chromosomal location) was expected to be found in Kitaake. By using SYNMAP (Lyons and Freeling, 2008), we identified 1002 allelic pairs (representing 90.5% of the total number of loci) between Nipponbare and Kitaake (Data S4). In addition, we noticed that for three NLR gene pairs located close to each other on chromosome 9 in the Nipponbare genome, three consecutive genes on chromosome 3 of the Kitaake genome were found with 100% identity with regards to their predicted coding sequence. The intergenic sequences of these two regions also had a high level of identity (99% over 40.5 kb), suggesting that these three genes are located in a translocated region of the genome.

First, to assess the impact of re-annotations on the number of LRR motifs in the alleles, the number of LRR motifs

**Figure 4.** Schematic representation of the annotation transfer strategy between closely related genomes.

(a) Identification of LRR-CR homologous regions. Nipponbare LRR-CR proteins were used to search regions of interest in the Kitaake genome using tBLASTx. BLAST hits with over 65% identity were ranked in the LRR-CR query protein sequence order and used to define the region boundaries. If the filtered BLAST hits within a Kitaake region covered more than 50% of the query LRR-CR sequence, then the Kitaake sequence of this region was extracted and linked to the Nipponbare LRR-CR query protein.

(b) Determination of gene models. The process strives to give a gene model for each region of interest identified in the Kitaake genome. The annotation is attempted in three consecutive steps. If the model from one step is unsatisfactory, i.e. gives an alignment of poor quality with the Nipponbare query protein, the process goes to the next step for this region. At the end of the third step, gene models that remained unsatisfactory were manually checked. This process allowed us to annotate 1046 genes in the Kitaake genome.
predicted in Nipponbare was compared with the number of LRR motifs predicted in Kitaake for each pair of allelic sequences. To obtain a precise annotation of the LRR motifs in each protein, we used the LRRPROFILER pipeline. The same procedure was also applied on allelic pairs identified between the publicly available annotations of Nipponbare and Kitaake. We observed a mean difference in LRR number per protein of 3.58 when comparing the publicly available annotations (IRGSP for Nipponbare and the only one that exists for Kitaake) (Figure 6 and Figure S5). This difference fell to 0.6 when our re-annotated data were compared. Using our curated annotations hence led to LRR number predictions that were much more consistent between Nipponbare and Kitaake alleles, and this trend was observed for all LRR-CR gene subfamilies. Moreover, the mean difference in LRR number still varied between LRR-CR gene subfamilies, with greater conservation of LRR motif numbers between LRR-RLK and LRR-RLP alleles than between NLR alleles.

Second, we analyzed the re-annotated allelic pairs related to their canonical or non-canonical status. Among the 1005 pairs (1002 allelic plus three translocated pairs), 688 (68.5%) were pairs of canonical gene models, 269 (26.8%) were pairs of non-canonical gene models and 48 (4.8%) were pairs of genes found to be canonical in only one of the two cultivars. Interestingly, 83.1% of the LRR-RLK pairs were canonical in both cultivars, compared with only 63.9% of the LRR-RLP pairs and 60.3% of the NLR pairs (Table 3).

To go further into this comparison, for each of the 1005 pairs of LRR-CR alleles, the fraction of exact matches along the cDNA pairwise global alignment (i.e. their percentage of identity) was computed. This cDNA identity was about 98.6% on average. The highest identity rate (99.3%) was obtained for alleles belonging to the LRR-RLK subfamily, followed by the NLR (98.2%) and LRR-RLP (97.9%) subfamilies. On average, non-canonical conserved gene pairs (NC/NC category in Table 3) had a lower identity level (97.9%) than conserved canonical gene pairs (99.4%). The lowest level of sequence identity (91.2%) was noted between gene pairs with one cultivar having a canonical form and the other cultivar having a non-canonical form (categories C/NC and NC/C in Table 3). Only 25 pairs of alleles (three LRR-RLK, four LRR-RLP, 17 NLR and one UC) shared less than 80% cDNA identity as a result of both deletions (up to 1.7 kb) and high sequence divergence. Two of these NLRs are located in the RGAS and Pik clusters that both hold resistance genes to rice blast disease (Table S3) (Li et al., 2007; Okuyama et al., 2011).

Genotype-specific LRR-CR genes in Nipponbare and Kitaake genomes

This gene presence-absence variation (PAV) analysis revealed that 48 LRR-CR genes were present only in Nipponbare and 58 LRR-CR genes were present only in Kitaake, of which 30 (six LRR-RLK, nine LRR-RLP, 17 NLR and two UC) and 34 (11 LRR-RLK, three LRR-RLP and 20 NLR), respectively, were canonical. Note that among the 11 LRR-RLK Kitaake-specific genes are the two Xa21 transgenes introduced into the KitaakeX sequenced genome (Jain et al., 2019). The Xa21 gene was initially cloned from the wild rice species Oryza longistaminata (Song et al., 1995). We indeed identified these two transgenes at positions 28,161,378 and 28,165,947 on chromosome 6, in accordance with published data (Jain et al., 2019). Among the Nipponbare-specific genes, two LRR-RLK (OsLP2 and RLCK354), three NLR (RPR1, STA260 and Osh359-3) and one UC (Bph33) have been named previously (Hu et al., 2018) (Sakamoto et al., 1999; Thilmony et al., 2009; Yao et al., 2018).

The genotype-specific genes were not evenly distributed on the genomes. Most of them, 72.9% (35/48) and 60.3% (34/56) respectively, were found in Kitaake and Nipponbare. The remaining 25.4% (12/48) and 36.3% (21/56) were found in both genomes; these genes were not considered as completely specific to one cultivar.

Figure 5. Proportion of canonical and non-canonical loci per gene subfamily in our Nipponbare and Kitaake expert annotations. Percentages were calculated per gene subfamily. The inner circle provides the number of loci per family, with a different color for each. The outer circle shows a lighter/darker version of the loci family color to represent the fraction of the non-canonical/canonical members, respectively, within this gene family.
(35/58) of the Nipponbare- and Kitaake-specific loci, respectively, were located on chromosomes 2, 11 and 12. On these chromosomes, some gene clusters were entirely composed of genotype-specific genes (Figure 7a). Other genotype-specific genes were found dispersed in regions containing conserved allelic pairs (Figure 7b). Chromosome 11, which also contained about a fifth of all LRR-CR genes, hosted 43 of the 106 (40.6%) cultivar-specific loci. Moreover, for more than half of these canonical genes (38 out of 64) the highest homology found in the Nipponbare or the Kitaake proteome is <80% of identity. Note that among these 38 genes, five Kitaake genes and seven Nipponbare genes have more than 95% of identity with indica cultivar proteins. Thus, the divergence of these genotype-specific proteins, related or not to the breeding histories of these varieties, highlights the variability of the LRR-CR repertoires between these two closely related accessions.

Finally, we took advantage of having the LRR-CR repertoire for both Nipponbare and a second rice genome to quantify putative sequence errors in the Nipponbare assembly. Among the 306 Nipponbare non-canonical genes, 241 (78.8%) presented at least one nonsense mutation also found within the Kitaake allele. These mutations were identified: (i) Nipponbare-specific genes (18 genes, 27.7%); (ii) Kitaake allelic canonical genes (19 genes, 29.2%); (iii) Nipponbare genes that have been classified as non-canonical for a different reason than the non-canonical Kitaake allele (six genes, 9.2%); and (iv) genes for which the 'RefSeq' data of NCBI reported a potential sequence error in Nipponbare (22 genes, 33.8%). The mutations observed in 18 and 40 genes (89.2%) were validated by the FLcDNA library and SRA, respectively. For four genes, no hits were obtained (6.2%). For the three remaining genes, a genomic sequence error was detected. The first one contained an ‘N’ that generated a frameshift, the second one had a small inversion of 24 bases that turned out to be erroneous and the third one had a wrong indel. These three genes, belonging to the NLR subfamily, were tagged in the data sets. These genes have not yet been described in the literature.

DISCUSSION

In recent years, in the wake of the gigantic volume of genome sequenced data available, it was exciting to undertake

© 2021 The Authors. The Plant Journal published by Society for Experimental Biology and John Wiley & Sons Ltd., The Plant Journal, (2021), doi: 10.1111/tpj.15456
They led to a large proportion of inconsistent gene models appeared to be suitable overall for many gene families, but other genes such as TFs. Automatic annotation pipelines differences were greater for LRR-CR genes compared with the gene models (Figure 2 and Figure S3; Table 1). These the number of LRR-CRs assigned to each subfamily and discrepancies regarding the total number of LRR-CR genes, for the Nipponbare rice reference genome showed major Our comparison of the three publicly available annotations complex multigenic families, such as LRR-CR, and even more so time-consuming task, especially when dealing with many plant genomes. Despite that automatic annotation tools are continuously improving, and remain essential at the genome level, human expertise is clearly still needed to achieve the level of annotation accuracy suitable for finer and deeper analyses. Today, we have finally undertaken this re-annotation work because we are convinced that these curated data are required to produce new reliable results on the evolution of these gene families, especially in the current pangenomic era. Here, we describe a new so-called ‘comprehensive’ annotation strategy. We hope that this annotation process will gain its Automatic annotations give inconsistent gene models on complex multigenic families Our comparison of the three publicly available annotations for the Nipponbare rice reference genome showed major discrepancies regarding the total number of LRR-CR genes, the number of LRR-CRs assigned to each subfamily and the gene models (Figure 2 and Figure S3; Table 1). These differences were greater for LRR-CR genes compared with other genes such as TFs. Automatic annotation pipelines appeared to be suitable overall for many gene families, but they led to a large proportion of inconsistent gene models when annotating complex multigenic families like LRR-CR. The annotation of fast-evolving multigene families is especially challenging for automatic approaches because a high duplication rate is often accompanied by a loss-of-function process (pseudogeneization) for many copies through, for instance, mutations like nucleotide substitutions, which may introduce premature stop codons or indels, in turn generating frameshifts. This can lead to the presence of several gene copies sharing high sequence similarity even though some of them may contain nonsense mutations, frameshifts or be truncated. The annotation of gene copies harboring nonsense mutations is problematic compared with the initial unaltered copy. Some pipelines will be able to detect the entire coding phase but will introduce false introns to sidestep stop codons or frameshifts in order to retrieve a putatively translatable CDS (Figure 3b). Indeed, we noticed that the MSU automatic annotation tended to sidestep nonsense and frameshift mutations by introducing short introns. Such errors were observed previously by Meyers when re-annotating the A. thaliana NLR gene family (Meyers et al., 2003). Two arguments strengthen the assertion that such introns are false: (i) such introns are never found in more than one copy, whereas the intron positions are known to be well preserved between closely related copies; and (ii) sequence comparisons performed against recent paralogs (or orthologs from close relative species) have shown that the sequences of these wrongly annotated introns are always clearly homologous to coding sequences in other gene copies. Among the intron gain mechanisms, intronization (i.e. the process by which an exonic sequence is changed into an intron by mutation accumulation) is a complex process that is not yet very well documented or understood (Roy, 2016; Yenerall and Zhou, 2012). If it really occurs in genomes, it implies that a sufficiently long period of time must have passed for these mutations to occur and generate novel splicing sites. It is
thus very unlikely that so many new introns arose in such a short period of time, as revealed by the low level of divergence between these genes and their paralog and/or ortholog counterparts. Other annotation pipelines, such as that of the IRGSP consortium, are more conservative in the sense that they give gene models with a more biologically meaningful expected structure, e.g. truncated proteins, in accordance with the presence of the first premature stop codons (either in-frame or caused by a frameshift; Figure 3b). This conservative choice could likely explain why we found more sequences classified as LRR-RLP from the IRGSP annotation than from the two other annotations (Table 1). Indeed, any LRR-RLK with a premature stop codon somewhere before the kinase domain would be considered as LRR-RLP (Figure 1). The annotation inconsistencies that we pinpointed here were observed for LRR-CR genes and did not question the overall quality of the three available rice genome annotations. They highlighted the limits of automatic annotation pipelines to annotate such complex multigene families and the consequences that given pipeline decision rules may have when drawing evolutionary conclusions.

The comparisons of the different gene models proposed by the three Nipponbare annotations led us to undertake a manual curation of the LRR-CR gene family. We are not the first to get involved in this painstaking but necessary work. Several high-quality studies have been based on re-annotated data, particularly in A. thaliana (Meyers et al., 2003; Van de Weyer et al., 2019). Expert annotations could also contain errors, of course, but expert curation limits their number. Opting exclusively for automated annotation should be avoided or otherwise operators should be aware that these annotations may contain errors induced by gene family specificities. These biases must be known and understood to avoid drawing misleading conclusions.

The expert Nipponbare rice genome contains more than 1000 LRR-CR loci, of which 30% have a non-canonical gene model

We curated LRR-CR loci in the reference Nipponbare rice genome by first comparing the three publicly available annotations at each locus: IRGSP, MSU and NCBI. Our aim was to retrieve LRR-CR genes in their entirety and account for the coding sequences as they probably stood before mutation accumulation. We obtained evidence that the sequence portions that we included in our gene models were not random genomic sequences but instead parts of the original gene CDS, as shown by the recovery of protein domains belonging to LRR-CR genes (kinase, NB-ARC, TM; Figure S4). Man et al. (2020) reported seven cases of missed domains through probable annotation errors in rice. We have also identified and corrected these seven genes and recovered the same domains. However, because our search for annotation errors was exhaustive, we recovered a higher number of missed domains.

When a gene had a nonsense mutation (in-frame stop codon or frameshift), an unexpected splicing site, or no terminal stop or start codon, we tagged it as non-canonical. This canonical versus non-canonical classification was based solely on features observed in gene models and did not imply any judgements on gene functionality. Genes tagged as non-canonical spanned a wide variety of cases, some of which could very likely not be translated into a functional protein while others may have had a function. As a first example, mutations inducing a premature stop codon could lead to a shorter protein that might sometimes perform the same function. Yet in many other cases shorter proteins might not perform the same function, if able to perform any function at all. Another example concerns the loss of the expected stop codon. When screening a sequence, a stop codon will eventually be encountered, but determining the functional consequences of this additional amino acid stretch would be impossible in silico. The same holds when the start codon is lost. Determining the criteria by which an alternative start codon (if any) may become the new start codon is a hazardous task. These few examples highlight the extent to which sorting out different functional scenarios is challenging. Moreover, mRNA molecules may play a regulating role, even if they cannot be translated as such, thereby justifying the need to annotate them. These reflections led us to voluntarily disregard such interpretations in our re-annotation process.

We observed that a third of the LRR-CR genes were non-canonical, but their proportion varied according to the gene subfamily (Table 2). A lower proportion of LRR-RLK genes were non-canonical (15%), compared with LRR-RLP (33%) and NLR (36%). The LRR-RLK subfamily could be divided into 15–20 subgroups based on phylogenetic study findings, and the duplication rate was shown to be quite variable according to the subgroup considered (Fischer et al., 2016; Tang et al., 2010). Some subgroups, the genes of which have been described as mostly involved in developmental processes, have had a more stable copy number over the course of angiosperm evolution (Fischer et al., 2016). These genes are less prone to duplication and thus are less likely to generate copies accumulating nonsense mutations, thereby lowering the proportion of non-canonical genes when the entire LRR-RLK subfamily is considered. The higher proportion of non-canonical genes obtained for NLR and LRR-RLP suggests that these subfamilies generally have higher birth and death rates. A quarter of the LRR-CR genes required manual curation and were non-canonical (representing 83.5% of the curated loci and 89.5% of the non-canonical loci; Table S2). In fact, manual curation was conducted mainly when none of the three annotations gave satisfactory gene models (such as the example presented in Figure 3b). The high correlation
between non-canonical and curated loci was thus likely caused by the presence of mutations introducing ambiguities, which are overcome to different extents by the three annotation pipelines. A step forward would be to improve the annotation tools so that they deal differently with these nonsense mutations, e.g. including them in the sequences and indicating their presence without sidestepping them. To this end, annotation tools would have to predict non-canonical structures and tag them accordingly. To process such complex data, machine learning approaches are very promising (Mahood et al., 2020), but this implies having a significant learning corpus that has yet to be built.

We stress that this categorization of loci into canonical or non-canonical models could be impacted by the genomic sequence quality. Errors in the reference genome sequence could introduce errors in the gene models. In our curated data set, 27 non-canonical genes were tagged in NCBI data as harboring a difference between the RefSeq transcript sequence or protein and the Nipponbare reference sequence. The mutations jeopardizing the expected gene structure corresponded exactly to the positions where inconsistencies had been highlighted between the genomic and the RefSeq data. In order to appreciate the impact of errors when genes were categorized as non-canonical, we checked 65 of them in Nipponbare using both expression data and genome resequencing data. Only three probable errors were detected (one containing an 'N'), and four could not be validated. Moreover, among the 27 genes for which NCBI reported a potential error in the genomic sequence, 25 actually contained the identified nonsense mutation. Redundancies in LRR-CR gene sequences can give rise to ambiguities during both genome sequence assembly and expression data mapping, thus leading to errors (Torresen et al., 2019). Access to more specific re-sequencing data will resolve those potential inconsistencies. In the current state of the data, the reference genome errors identified concern less than 1% of the non-canonical genes.

LRR-CR repertoire in Kitaake, and comparison with Nipponbare

We propose a modular strategy to transfer our manually curated annotations to other rice genomes. We applied this strategy to annotate LRR-CR genes from the genome of the Kitaake cultivar, which also belongs to the O. sativa japonica subspecies. A comparison of the Nipponbare and Kitaake LRR-CR repertoires revealed an equivalent number of loci. The distributions of LRR-CR loci per gene subfamily, chromosome and category (canonical or not) were also consistent between these two cultivars (Figure 5).

In the Nipponbare genome, eight new LRR-CRs (one LRR-RLK, three LRR-RLPs and four UCs) were identified. These genes had not been previously annotated in any of the three publicly available annotations. In Kitaake, the same strategy enabled us to identify 114 new LRR-CR genes (48 of which were canonical). The higher number of unannotated LRR-CR genes in the Kitaake genome compared with the Nipponbare genome (114 versus eight) suggested that annotation inaccuracies had a greater impact on recently sequenced genomes that have not benefited from as much annotation investment as reference genomes.

A comparison of the LRR motif number for all allelic pairs between Nipponbare and Kitaake revealed a much greater difference in LRR number between alleles for publicly available annotations (ranging from 2.68 to 3.58), in comparison with our manually curated annotations (0.58), when the three subfamilies were all considered (Figure 6 and Figure S5). When publicly available annotations are considered, some rare allelic pairs harboring a very different number of LRRs may be truly different functional alleles. For instance, between two LRR-RLP alleles, one may contain a premature stop codon leading to the loss of a few motifs, but it may still have a biological function. It is important to identify such a pair. In our expert annotation alleles may share an identical number of LRRs, but such allelic pairs would be clearly identifiable because one of the alleles would be tagged as non-canonical whereas the other would be tagged as canonical. Moreover, in non-canonical alleles, the causal mutation, its position and impact on the gene (i.e. frameshift or premature stop codon) could be identified.

The difference in LRR motif number observed between allele pairs was greater for NLR than for the other subfamilies (Figure 6). This might be explained by the fact that NLR motifs are more variable and hence harder to detect (Ng et al., 2011), which could lead to apparent variations in the number of motifs in the two alleles. LRR motifs that have been found in NLRs differed from the common ‘plant-specific’ LRR consensus sequence, and were more irregular in terms of both length and residue conservation (Kajava, 1998; Kuang et al., 2004; Matsushima and Miyashita, 2012; Sela et al., 2012). Although we enhanced the LRR detection accuracy through the development of a new LRR HMM profile for NLR, it is still not exhaustive. This also suggests that the number of LRR motifs varies more in NLR than in other LRR-CR subfamilies.

High sequence similarity was observed between Nipponbare and Kitaake alleles (98.9% identity for cDNA) (Table S3), which was consistent with previous comparisons (Jain et al., 2019). However, some allelic pairs showed a lower identity level with a more ancient coalescent history between the two genomes. This heterogeneity may have been the consequence of the breeding programs from which these varieties were derived. The breeding process involves crosses with more or less closely related genotypes, sometimes from different subspecies, and may generate mosaic genomes (Santos et al., 2019). No allelic
pairs were found for 106 genes: i.e. 48 were specific to Nipponbare and 58 were specific to Kitaake. A majority of those genes were located in clusters on chromosomes 2, 11 and 12, which have already been described as containing a large number of LRR-CRs (Mizuno et al., 2020; Zhou et al., 2004) (Figure 7). Some clusters have also been shown to be less conserved (Mizuno et al., 2020). More than half of these genes were classified as canonical.

The methods we developed allowed us to undertake an exhaustive comparison of the LRR-CR repertoire between Nipponbare and Kitaake. Allelic pairs, including those hosting nonsense mutations in either or both genotypes, were described (Data S4). Genotype-specific genes were also identified and localized, again along with information related to the potential presence of nonsense mutations (Figure 7). These results were achieved through a combination of an expert annotation and its transfer to a second genotype for which a high quality de novo genome assembly was available. Validation of the LRR-CR annotations of Kitaake was not very time consuming compared with the initial work in Nipponbare, where each gene was investigated individually. Our study highlighted that investment in a combination of technologies would guarantee high-quality assemblies and annotations, especially when the discovery of allelic diversity is targeted (Zhou et al., 2020).

The tools and curated data sets that we generated in this study are available from: https://rice-genome-hub.southgreen.fr/content/geloc (data) and https://github.com/cgottin/LRRprofiler (tools). Note that we focused on developing a website where stop codons and frameshifts are easily identified. We believe that evolutionary studies and allele discovery initiatives for LRR-CRs would be more accurate and reliable when using our manually curated comprehensive annotations for these genes. Moreover, we feel that this comprehensive annotation approach should be widely adopted by the community in the light of the major potential benefits it provides.

**EXPERIMENTAL PROCEDURES**

**Genomes and annotation files**

Reference genomic sequences of Nipponbare (Kawahara et al., 2013) and Kitaake (Jain et al., 2019) *O. sativa* ssp. *japonica* cultivars were downloaded from the Rice Annotation Project Database (RAP-DB) website (https://rapdb.dna.affrc.go.jp) and the Phytozone website (https://phytozone.jgi.doe.gov/pz/portal.html). The general feature format (GFF) and fasta files with coding DNA sequences (CDs) and protein sequences for Nipponbare were downloaded for three different annotation projects: (i) the MSU 7.0 annotation was downloaded from the Rice Genome Annotation Project FTP server (http://rice.plantbiology.msu.edu); (ii) the IRGSP annotation files were downloaded from the RAP-DB website (https://rapdb.dna.affrc.go.jp); and (iii) the NCBI annotation (release 102) annotated by the NCBI Eukaryotic Genome Annotation Pipeline was downloaded from the NCBI website (https://www.ncbi.nlm.nih.gov). The IRGSP annotation consists of two gene sets (‘genes supported by FL-cDNAs, ESTs or proteins’ and ‘computationally predicted genes’) that were concatenated for the analyses (Sakai et al., 2013).

**LRRPROFILER implementation**

The LRRPROFILER pipeline was implemented in two steps (Figure S1). The first step involved the iterative refinement of LRR HMM profiles specific to a gene subfamily (LRR-RLK or NLR) and proteome (Figure S1; inspired by Ng et al., 2011). Only LRR-RLK and NLR were considered for profile refinement because they contain a specific domain (i.e. kinase and NB-ARC domains, respectively), thereby allowing the clear identification of the subfamily to which they belong. A set of candidate protein sequences was identified from a given proteome to refine the specific LRR profiles. This set was composed of either LRR-RLKs identified with iTAK (Zheng et al., 2016) or NLRs identified with the PF00931 Pfam NB-ARC profile. A first round of LRR motif detection was performed in either of the candidate protein sets using HMMSEARCH (HMMER; Eddy, 2011) with the SM00370 LRR profile from the SMART database. Motifs of 20–26 amino acids in length were extracted, aligned with MARF (Katoh and Standley, 2013) with default parameters and a new profile was built from the alignment using HMMBUILD (HMMER; Eddy, 2011). This process was repeated using the HMM LRR profile built at the previous iteration to search again for LRR motifs in the considered protein candidate set. At each iteration, the sum of the amino acid lengths of the detected LRR motifs was calculated. The process stopped when three iterations (not necessarily consecutive) resulted in a decrease of the statistics. Finally, the process retrieved the HMM LRR profile identifying the maximum number of LRR motifs in the candidate protein set.

The second step of the LRRPROFILER pipeline consisted of the identification of LRR-CRs proteins present in a given proteome, the annotation of their functional domains as well as their classification into a gene subfamily: LRR-RLK, LRR-RLP, NLR or UC (Figure S1). Six publicly available LRR HMM profiles from the SMART database, i.e. SM00364 (LRR_BAC), SM00365 (LRR_SD22), SM00367 (LRR_CC), SM00368 (LRR_RI), SM00369 (LRR_TYP) and SM00370 (LRR), in addition to the newly built LRR profiles obtained in the first step were used to detect LRR motifs in the complete proteome under consideration using HMMSEARCH. An annotation of the LRR domains, containing the start and end positions of each LRR motif, was part of the output. The annotation of each protein was then supplemented using publicly available profiles for other functional domains: TIR (PF10582), TIR_2 (PF13676), Malectin (PF11721), Malectin-like (PF12819), RPW8 (PF05659), Cys-Pairs (Dievart and Clark, 2003; Dufayard et al., 2017), F-box (PF00646) and FBD (PF08387), NB-ARC and kinase domain annotations were retrieved from the first step, whereas transmembrane domains (TMs) were detected with TMHMM 2.0c, with default parameters (Sonnhammer et al., 1998). The subfamily assignment of each identified LRR-containing protein was deduced from its domain structure. Proteins were classified into the LRR-RLK subfamily if they contained at least one LRR motif and a kinase domain, and sometimes other domains such as the malectin, malectin-like, Cys-pair and TM domains. Proteins were classified in the NLR subfamily if they included an NB-ARC domain and at least one LRR motif, sometimes with a TIR or an RPW8 domain. The LRR-RLP subfamily included proteins with LRRs plus a TM, malectin, malectin-like and/or Cys-pair, or LRR-only structures when at least 13 plant-specific LRR repeats were detected. Proteins containing an F-box or an FBD domain in addition to LRRs were classified as F-box-LRR. All other LRR-containing proteins were ranked in the UC group, and for these we performed a
BLASTp search with default parameters against the other gene sets (LRR-RLP, LRR-RLK, NLR and F-box) to estimate their probable membership of one of these gene subfamilies. F-box proteins were removed from our data sets and not considered further in the analyses. We ended up with four gene sets: LRR-RLP, LRR-RLK, NLR and UC.

At the end of the construction phase, the complete LRRPROFILER pipeline was tested on the manually reviewed A. thaliana protein data set downloaded from the Swiss-Prot section (https://www.uniprot.org) (Data S1; Figure S2; Methods S1; Table S1) (Boutet et al., 2007) of the UniProt databank (The UniProt Consortium, 2019). This set was composed of 15 818 sequences. Domain and repeat information was also extracted from the database, in particular the number of LRR motifs per sequence and the gene subfamily to which it belonged (LRR-RLP, LRR-RLK, NLR, etc.).

Rice transcription factor data set

Transcription factor genes (TFs) were identified in the proteome predicted from the three publicly available annotations of the Nipponbare rice reference genome using ITAK (Zheng et al., 2016). Nine subfamilies were considered: C2H2, FAR1, MYB-related, WRKY, NAC, AP2/ERF-ERF, bHLH, bZIP and MYB.

Annotation transfer from Nipponbare to Kitaake

The first phase consisted of locating regions of interest in the Kitaake genome, i.e. regions homologous to Nipponbare LRR-CR loci (Figure 4a). Nipponbare LRR-CR protein sequences from our expert annotations were aligned with the Kitaake genome using tBLASTn (Altschul et al., 1990). Only high scoring pairs (HSPs) with more than 65% identity with Nipponbare LRR-CR protein fragments and spanning at least 50% of the Nipponbare query protein were retained. To define coherent candidate regions in Kitaake, HSPs from the same Nipponbare query protein had to be located less than 5000 bp apart, except when the Nipponbare homologous gene queried had a longer intron. In that case, the Nipponbare intron length plus 500 bp was used as the upper bound for the distance separating Kitaake HSPs. Multiple regions of interest could be found for a single Nipponbare protein. This allowed us to annotate genes duplicated in the Kitaake genome even if a single gene copy was present in the Nipponbare genome. In a second phase, gene model determination was attempted in three consecutive steps for each region of interest (Figure 4b).

Regions that could not be successfully annotated at a given step passed to the next step. In the first step, the Nipponbare query exons are mapped to the target Kitaake region of interest with BLASTn. A gene model was then reconstructed based on ordered HSPs. The gene model reconstruction quality was checked by comparing the predicted protein with that of Nipponbare using BLASTp. The gene model was retained if all expected exons were present and the Kitaake protein sequence had more than 90% identity with the Nipponbare protein sequence. Otherwise, the annotation of this region was delegated to the second step. In the second step, the EXONERATE cdna2genome model (Slater and Birney, 2005) was run independently for every remaining query/target pair. The EXONERATE output GFF file was parsed to construct the target gene model and to document putative frameshift positions. Again, the Kitaake predicted protein was compared with the Nipponbare query sequence with BLASTp and retained if the coverage and identity were above 90 and 75%, respectively. Otherwise, the annotation of this target region was delegated to the third step. In the third step, the remaining loci were reconstructed with the EXONERATE protein2genome model.

This model is better at finding the correct reading frames when the target and model loci are more divergent, but it fails to correctly annotate type-1 and -2 splicing sites (intron/exon junction falling inside a codon). This problem arises because it uses the same reading frame to translate the whole genomic sequence (the six reading frames are tested, but each resulting translation just uses one of them). To overcome this issue, intron junctions are then corrected with a PYTHON script that looks for canonical splicing sites in a range of two nucleotides before and after the current junctions. Finally, gene models highly divergent from the Nipponbare query sequence, with multiple premature stop codons or without start or terminal stop codons, and overlapping frameshifts are tagged to be checked manually.

Identification of alleles between Nipponbare and Kitaake

We used SYMAP (Lyons and Freeling, 2008) to identify LRR-CR allelic pairs, i.e. genes with the exact same chromosome position in Nipponbare and Kitaake. SYMAP was developed to identify orthologous genes between different species based on microcolinearity conservation, and it identifies blocks of genes of conserved order and position. It retrieves a list of relationships between genomic repertoires of two genomes. We identified alleles by first selecting genes for which SYMAP found a reciprocal relationship, i.e. a relationship found in both Nipponbare-Kitaake and Kitaake-Nipponbare comparisons. Genes for which allelic relationships could not be unambiguously resolved by SYMAP were manually resolved, when possible, using VISTA (Mayor et al., 2000) and ARTEMIS (Carver et al., 2012).

DATA AVAILABILITY STATEMENT

All of the data files (gff and fasta files) are available from the dedicated website (https://rice-genome-hub.southgreen.fr/content/geloc) and from the open data repository Zenodo (https://doi.org/10.5281/zenodo.5110015).

A new identifier was allocated to each LRR-CR gene unraveled by this procedure. These identifiers use the <OSJnip_ChrXX_00000000> or <OSJKit_ChrXX_00000000> pattern for Nipponbare and Kitaake loci, respectively, with XX being the chromosome number followed by the start codon position of the coding sequence (CDS) on the chromosome (Data S2 and S3).

According to the Multiple Alignment of Coding Sequences (MACSE) convention (Ranwez et al., 2018; Ranwez et al., 2011), indels causing frameshift mutations have been pinpointed by the presence of one or two ‘‘’‘ characters in the nucleotide sequences of non-canonical genes and are available in an additional specific data set.
