HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
Resilience from perturbation of architectural scheme through planting varies largely in *Pinus pinaster*

11th ISRR meeting, 24-28 May 2021

**Introduction:** Planting is a widespread propagation technique for woody plants. Container-growth and plantation is likely to heavily alter root architecture and thus modify anchorage. The Landes forest is located South-West France and produces 20% of french wood, it is mainly composed of intensively managed even-aged stands of *P. pinaster* (Ait.). Most reforestation is made by planting genetically improved varieties, from seeded nursery stock. Soils are eritic to albic spodosols which are acidic, sandy, and lenses of cemented spodic horizon can occur.

Root system architecture is a key component in mechanical stability of trees. In their first 15 years, pines are mainly anchored by a rigid vertical and deep taproot (*Danquèchín Dorval 2016*). Older trees are anchored by a rigid cage mainly composed of regularly space shallow roots from which branch secondary sinkers (*Danjon et al. 2005*). The main framework of the central part of the root system is established at 4-years-old with a clear identification of root types (*Saint Cast et al. 2020*).

In this study, we characterize the deformations of root systems of *P. pinaster* saplings grown in containers and planted in the field. Incidence on root system architecture is analysed.

**MATERIAL AND METHODS**

Three hundred 3 to 5-years-old *P. pinaster* saplings planted in 16 forest stands were uprooted with hand tool and digitized using a magnetic field Polhemus 3D digitizer (*Danjon & Rebens 2008*). They were compared to 30 direct seeded trees from one stand. The resulting database contained 67000 segments and 102500. We set up and used an original architectural analysis to characterize deformations and thus root type modifications in order to examine the resulting root architecture and potential stability.

**RESULTS**

**Stump-taproot axis:** The root system of planted trees was 1.8 cm deeper on average than seeded trees, few plugs showed on the soil surface or were crushed. Plug tortuosity averaged 14% in the planted trees and 5% in the seeded trees, below plug and soil zone tortuosity was weak. In the below-plug zone, vertical deviation of the first order root peaked at a 40° average vs. 20° in the seeded trees (fig 5). Overall, 17% of planted trees have a non vertical taproot vs. 1.5% for the seeded (fig 6). When the taproot was not vertical in the 4 cm long below-plug zone, 30% of the taproots did not recover their verticality. Conversely, only 7% lost it when the below plug zone was vertical (fig 7).

**Potential shallow roots:** The distribution of these roots along the first order root was not modified by container planting and the largest ones grew from the upper plug zone. Heavy deformations of laterals due to nursery growth in grilled and vertically grooved containers and by planting were located within 6 cm radial distance from the taproot (fig 8). When the 6 first cm of a lateral root was maintained in a non-horizontal position, 27% of these originally shallow roots grew as oblique roots and 17% as sinkers. Conversely, when the horizontal azimut, 89% of the lateral roots remained shallow (fig 9). The largest azimuth angle between shallow roots (LABS) is largely determined by their number at 12 cm radial distance from the first order root (p = 0.7), which is lower when shallow roots lose their plagiogravitropism (fig 10). The planted stand showed significantly larger clustering of azimuth of their shallow roots resulting in significantly larger angle between shallow roots (p = 0.84).

**Conclusions:** The studied planted stands showed low mortality and a small number of badly planted seedlings. They displayed a very large variability in type and degree of deformations which could not be related to variables like the planting season or the type of soil preparation. About half the planted trees showed a good resilience as they were able to grow a root system which is likely to provide a good anchorage, other trees possess a non-vertical or weak taproot or show large LABS, except in planted stands b3, e3 and f3 where less than 20% of the root systems has no acceptable defect. We concluded that change in root tropism through nursery growth, planting and initial root regrowth is likely to weaken the anchorage of the trees both in juvenile or mature stage. Thus orientation of root ends at interface of the plug and the soil, just after plantation is a major issue for tree anchorage.
