10 **Abstract**

11 This study proposed to develop a model coupling hydrodynamics and mass transfer in order to gain

12 an understanding of measurements taken on air-water bubble columns with low gas hold-up. Three

13 experimental datasets with various operating conditions (water quality, liquid height, air flow range)

14 were chosen. The model analyzes and interprets the significant impact of the local hydrostatic

15 pressure and the effects of contamination on hydrodynamic and mass transfer parameters. The

16 oxygen concentration in gas significantly depletes with the distance from diffusers, which explains

17 the difference between the calculated mean of the local $<k_La>$ and global K_La coefficients. This

18 difference is highly significant for a high bubble column and/or systems with a low mean bubble size.

19 The impact of water quality on mass transfer can be characterized by the contamination angle using

20 comprehensive 1-D modeling and highlights a differentiated impact on the hydrodynamic or mass

21 transfer parameters.

25

26 **1. Introduction**

27   In the domain of water and wastewater treatment and recovery, gas–liquid reactors are often used

28   to perform gas–liquid oxygen mass transfer. In particular, air bubbles are injected in aeration tanks to

29   provide microorganisms with the oxygen they require for their growth. Aeration systems in these

30   processes must be efficient in terms of mass transfer coefficients, easy to construct, with no moving

31   parts and a low pressure drop through the air diffusers (Manjrekar 2016). In this study, an analogy is

32   made between bubble columns and wastewater aeration tanks, since they can both operate in the

33   bubbly flow regime with similar heights and gas hold-up ranges. Indeed, using a deep bubble column

34   allows one to reproduce the water heights and gas–liquid contact times encountered in aeration

35   tanks (Gillot and Héduit 2008, Duran et al. 2016, Baeten et al. 2020). Similarly, air flowrates can be

36   set to obtain gas superficial velocities and gas hold-ups ranges used in aeration tanks (Shah et al.

37   1982, Duran et al. 2016, Amaral et al. 2018). This analogy aims at helping reach a better

38   understanding of fundamental phenomena that affects gas–liquid mass transfer in the bubbly flow

39   regime, in order to optimize the aeration systems that remain the main energy consumer in water

40   resource recovery facilities (Rosso and Stenstrom 2005, Longo et al. 2016).

41   For systems with low gas hold-ups (< 5%) and fine bubble diffusers, air bubbles are spherical or

42   ellipsoidal with few coalescence and break-up phenomena (Talvy et al. 2007a, Colombet et al. 2015).

43   However, bubble coalescence is more likely to occur in systems with denser bubble swarms and

44   higher gas hold-ups and bubble diameters. In an air–water bubble column with fine bubble diffusers,

45   the homogeneous flow regime without coalescence can be maintained under a transitional gas

46   superficial velocity between 0.04 and 0.08 m/s (Mudde et al. 2009). In Besagni et al. (2016), the

47   coarse gas sparger used led to an early disruption of the bubbly flow due to both non-uniform

48   distribution and changes in bubble size generation. Loubière et al. (2003) also pointed out that

49   bubble size variation depended upon the type of diffuser with a flexible porous membrane, the initial

50   bubble size increases as the superficial gas velocity rises, whereas when using a rigid orifice, bubble

51   size varies slightly depending on superficial gas velocity.

In air-water systems, the effect of bubble contamination on mass transfer is another frequently observed process and is mainly due to surfactants (Pöpel and Wagner 1994; Capela et al. 2002; Sardeing et al. 2006, Rosso et al. 2006, Jimenez et al. 2014) as well as aqueous salt solutions such as in biological media (Zlokarnik 2005). Contaminated bubbles yield lower mass transfer coefficients than perfectly clean bubbles, even though the level of bubble contamination may be difficult to quantify (Sardeing et al. 2006, Xu et al. 2018).

Water height also has an impact on overall mass transfer (Deckwer et al. 1974, Giovannettone and Gulliver 2008) since the gradients of the gas–phase composition and pressure appear to have highly interactive non-linear effects (Baeten at al. 2020). First, bubble diameter varies with hydrostatic pressure (Capela et al. 2002, Giovanettonne et al. 2009, Fayolle et al. 2010, Amaral et al. 2018), which has an influence on the gas–liquid interfacial area. In addition, the oxygen saturation concentration varies depending upon column height (Rubio et al. 1999) and the dissolved oxygen concentration profile at steady state can be very pronounced, suggesting local variation of the transfer rate even if the overall net transfer of oxygen is close to zero (Giovannettone and Gulliver 2008). The combination of these phenomena induce oxygen depletion in air bubbles, essentially explained by competition between the transfer rate and bubble convection (Talvy et al. 2007a, Giovanettonne and Gulliver 2008, Baeten et al. 2020).

To provide a comprehensive description of gas transfer inside deep air-water bubble columns, the classical one-dimensional two-fluid model (Wallis 1969, Cockx et al. 1997, Camacho-Rubio at al. 2001, Vitankar and Joshi 2002) developed in previous studies for airlift reactors, aeration tanks or bubble columns has been extended (Talvy et al. 2007a, Talvy et al. 2007b, Colombet et al. 2013). Since the transfer rate gradient increases with the height of the bubble column via the various well-identified mechanisms discussed above, all these phenomena need to be combined in a new model structure where both hydrodynamics and mass transfer are solved together to consider the effect of pressure and gas depletion.

77 One-dimensional (1-D) models are simple but rigorous and appear to be relevant when applied to

78 bubble columns since gas flows are mainly in the vertical axis. Most existing models consider a

79 constant superficial gas velocity since they apply to low height columns (Talvy 2007b, Colombet et al.

80 2013) and thus the pressure effect can be ignored. However, this may not be the case for columns

81 with a high liquid height, as shown in studies taking the effect of pressure on gas solubility into

82 account (Dhaoudi et al. 2008), or both gas solubility and gas flowrate (Giovanettone and Gulliver

83 2008, Baeten et al., 2020). In these investigations, the overall mass transfer coefficient K_La was

84 considered, even though representing hydrodynamic variations together with changes in mass

85 transfer (separating k_L from a) would be more useful to better interpret experimental results. In this

86 context, the aim of this study was to develop a model that couples hydrodynamics and mass transfer

87 in order to gain an understanding of measurement results obtained on systems with low gas hold-up

88 under different configurations. Based on a literature review, the correlations that can be used to

89 represent hydrodynamic and mass transfer phenomena (drag coefficient, mass transfer coefficient,

90 collective bubble effects due to high gas hold-up) were identified. The simulation results were

91 compared to observed data obtained in three experimental setups showing contrasting operating

92 conditions (in terms of water height, gas hold-up, bubble diameter and interface contamination).

93 Their specific relevant hydrodynamic and oxygen transfer phenomena were analyzed by modeling

94 and simulation. To begin, after presenting the experimental datasets, the different processes

95 considered in the comprehensive model are described. Subsequently, the simulated results are

96 compared with the experimental data to choose between the different options concerning the model

97 structure (closure relations) and to interpret the experimental results obtained under varied

98 operating conditions.

99

100 **2. Material and methods**

101 The proposed 1-D model is used to investigate the results extracted from three experimental

102 datasets obtained in clear water (Colombet et al. 2015, Duran et al. 2016, Amaral et al. 2018).

103   2.1 Experimental datasets

104   The database is composed of three experimental datasets obtained in bubble columns showing a low

105   gas hold-up (less than 6%). They were selected because of their wide range of operating conditions

106   (superficial gas velocity and gas hold-up) and the availability of data. Table 1 presents the main

107   operating conditions for the three experimental datasets.

108

109   **Table 1. Experimental conditions for the bubble column datasets**

| Dataset	Continuous fluid phase	Bubble sparger type	H_L (m)	d_B expressed at P_{atm} ($\times 10^{-3}$m)	j_g at P_{atm} ($\times 10^{-3}$m/s)	ε_g (%)	Reference
D1	Tap water	EPDM membrane	1.30	1.5 - 1.8	0.3 - 1.2	0.1 - 0.4	Amaral et al. (2018)
D2	Tap water	EPDM membrane	4.40	3.0 - 4.0	2.0 - 4.5	0.5 - 1.5	Duran et al. (2016)
D3	Filtered tap water	Capillaries	0.76	2.3 - 3.4	2.0 - 15.5	0.5 - 6.0	Colombet et al. (2015)

110   With : d_B mean bubble diameter, P_{atm} standard atmospheric pressure (1013 hPa), j_g superficial gas velocity, ε_g

111   overall gas hold-up, H_L liquid height.

112

113   The water quality slightly differed from one dataset to another. In particular, the liquid used in

114   Dataset D3 was filtered tap water (15 µm cutoff threshold) and tap water for D1 and D2.

115   Datasets D1 and D2 were obtained in bubble columns equipped with EPDM membrane diffusers,

116   similar to the ones installed in full-scale aeration tanks. For Dataset D1, the water height was quite

117   low (1.30 m). The superficial gas velocity and associated mean bubble size and gas hold-up were

118   significantly lower in comparison to the other datasets. Dataset D2 corresponds to the experimental

119   bubble column with the highest liquid height (4.5 m) in the lower range of liquid heights found in

120   industrial aeration tanks, which allows for the study of the impact of hydrostatic pressure on

121   hydrodynamics and mass transfer phenomena. A more complete description of this experimental

122   dataset is provided in the following section, given that clear water results are not fully described in

123   the published article (Duran et al. 2016).

124   Figure 1 presents hydrodynamic and mass transfer characteristics as a function of the superficial gas

125   velocity for Dataset D2.

126

(i)

(ii)

(iii)
127   **Figure 1.** (i) Mean bubble Sauter diameter and mean bubble eccentricity measured at 1 m in height from the

128   diffuser, (ii) overall gas hold-up (ε_g) and mean bubble rise velocity (U_b) at 20°C, (iii) overall oxygen transfer

129   coefficient $K_L a$ expressed at 20°C and gas–liquid interfacial area (a) as a function of the superficial gas velocity –

130   dataset D2

131

132   The mean bubble Sauter diameter increased from 2.2 to 3.6 mm with an increase in the superficial

133   gas velocity (j_g) from 1.2 to 4.6 mm/s. The effect of the airflow rate on bubble size was more

134   significant at lower superficial gas velocities because the membrane stretches and the pore size

135   increases under the effect of the pressure associated with the airflow rate. Concerning the bubbles'

6

136 shape, their eccentricity slightly increased from 1.4 to 1.7 with the increase of the superficial gas

137 velocity. Classically, the overall gas hold-up is a linear function of the superficial gas velocity, whereas

138 the oxygen transfer coefficient follows a power law. The mean bubble rise velocity deduced ($U_b=j_g/\varepsilon_g$,

139 for homogeneous distribution of gas along the column's surface) slightly decreased as the superficial

140 air velocity increased. The reduction of U_b can be attributed to the collective effects (the interaction

141 between bubbles) that ended up with higher bubble drag coefficients, as explained by Colombet et

142 al. (2011). Since the estimated K_L coefficient ($K_L=K_La/a$) remains almost constant within the range of

143 the j_g studied, the increase in the overall oxygen transfer coefficient (K_La) is mainly related to the

144 increase in the interfacial area (estimated form d_{bs}, ε_g and bubble eccentricity; see Eq. 30 below).

145 Dataset D3 includes a wide range of superficial gas velocities and gas hold-up, even though the water

146 height is lower in comparison with the other datasets. The bubble injection system consists of a

147 network of stainless steel capillaries (with an inner diameter of 0.2 mm), that makes it possible to

148 obtain a homogeneous bubble swarm. In contrast, the diffuser of the two other datasets, a porous

149 EPDM membrane, provides a more heterogeneous initial bubble size distribution as commonly found

150 in water treatment. In order to focus on low gas hold-up systems, the data considered were limited

151 to gas hold-up lower than 6%, despite the wider range in the complete study (Colombet et al. 2013).

152

153 On the basis of transfer numbers (N_T), these datasets were compared with different previous

154 databases from lab-scale (Capela et al., 2002) to full-scale aeration tanks (Fayolle et al. 2010, Fayolle

155 et al. 2011). This dimensionless group ($N_T = \frac{K_La_{20}}{j_g}\left(\frac{\mu_L^2}{\rho_L^2 g}\right)^{1/3}$) defined by Zlokarnik (1979) and

156 Roustan (1996) has the same physical meaning as the specific standard oxygen transfer efficiency

157 (SSOTE in %) per meter of diffuser submergence for clear water operating conditions (Gillot et al.

158 2005). Figure 2 presents the transfer number as a function of the mean Sauter bubble diameter for

159 the different databases selected and datasets D1–D3.
Figure 2. Transfer number (N_T) versus bubble Sauter diameter for selected databases (lab-scale [Capela et al., 2002] and full-scale [Fayolle et al., 2010 and 2011]) and datasets 1–3.

For reactors with different configurations (from pilot scale to full-scale reactors), the transfer number (N_T) seemed to be determined by the Sauter diameter, which fixes the bubble surface mobility and the G-L interfacial area by controlling the overall gas hold-up. The results also clearly demonstrate that the transfer number is an adequate scale-up factor for systems equipped with fine bubble diffusers. Likewise, through the comparison with data obtained at full-scale, these results validate the representativeness of the three datasets in terms of mass transfer mechanisms.

2.2. Two-Phase One-Dimensional Model

The proposed model is a 1-D model derived for low soluble gas mass transfer into a liquid in deep bubble columns, applied to an air–water system (O_2 is considered to be the only gas transferred). Since the calculated variables are homogenous and evenly distributed along the cross section, a 1-D approach can be considered. The model first calculates hydrodynamic variables (gas hold-up, changes in bubble diameter, gas velocity) considering steady-state conditions. Then, hydrodynamic results are used as input values to calculate the transient oxygen mass transfer from the gas phase to

177 the liquid phase. The impact of the oxygen transfer on the bubble size and associated hydrodynamics

178 is ignored.

179 Contrary to other existing 1-D models (Giovannettonne and Gulliver, 2008, Baeten et al. 2020), the

180 impact of pressure on gas superficial velocity and bubble diameter is taken into account and its

181 impact on gas hold-up and mass transfer is fully considered and analyzed. The model is based on a

182 simplified Eulerian two-fluid model such as reported in Talvy et al. (2007a,b), where mass balance for

183 the gas and liquid phases and momentum interactions between the two phases are considered. The

184 proposed model implies different hypotheses related to the considered system (oxygen transfer in

185 batch air-water bubble column with low gas hold-up): (i) the impact of the mass transfer on the

186 bubble size and associated hydrodynamics is neglected, (ii) no vertical liquid flow is considered, (iii)

187 the bubbly flow is homogeneously distributed along the cross-section of the bubble column and (iv)

188 coalescence is neglected. The column is discretized along its height (50 layers along z), so the

189 variables are calculated locally at each discretization point.

190 Table 2 summarizes the values considered for the fluid properties and the main parameters of the

191 model (T = 20°C and P_{ref} = 1 atm).

192

193 **Table 2. Physico-chemical properties of the system (T = 20°C and P_{ref} = 1 atm)**

Parameter	Value	Unit
Water density, ρ_L	998.2	kg/m^3
Water dynamic viscosity, μ_L	1.10^{-3}	Pa.s
Water surface tension, σ	73	mN/m
Air density, ρ_G	1.2	kg/m^3
Oxygen diffusivity in water, D	2.10^{-9}	m²/s
Gravity constant, g	9.81	m/s²
Temperature, T	20	°C
Atmospheric pressure, (P_{ref})	1	atm

194

195 2.2.1. Equation of the 1-D model

196 All variables were averaged along each cross section of the column in order to provide a simple 1-D

197 model. As an example, the local gas hold-up in a cross-section S is given in Eq.1 (Talvy et al., 2007b).

$$\varepsilon_k = <\alpha_k> = \frac{1}{S} \iint_A \alpha_k dS \qquad \text{(Eq. 1)}$$

198 where ε_k is the mean gas hold-up in the section, and α_k is the local gas hold-up at a specific point in

199 the section. For the velocities, only the averaged axial components are different from zero and

200 velocity vectors are thus reduced to scalars in the following.

201

202 2.2.2. Model structure: steady state hydrodynamic calculation

203 The hydrodynamic equations solved in the model are presented in the following sections.

204

205 2.2.2.1 Mass and flow rate conservation equation

206 The mass balance equation in a diphasic system is written as follows (Talvy et al. 2007a):

$$\frac{\partial \alpha_k \rho_k}{\partial t} + \nabla \alpha_k \rho_k \overline{U_k} = \overline{m_K} \qquad \text{(Eq. 2)}$$

207 where α_k is the volume fraction, ρ_k the density and $\overline{U_k}$ the average velocity of phase k, which stands

208 for gas (g) or liquid (l). The first term on the left side corresponds to mass variation over time in

209 phase k, the second to mass transport by advection in the phase k, and the term on the right side

210 ($\overline{m_K}$) corresponds to a statistical average mass transfer between the two phases.

211 In a 1-D system, Eq.2 becomes:

$$\frac{\partial (\varepsilon_k \rho_k)}{\partial t} + \frac{\partial}{\partial z} (\varepsilon_k \rho_k U_{kz}) = <m_k> \qquad \text{(Eq. 3)}$$

212 With a steady state flow and assuming that average mass transfer between phases implied in the

213 mass balance is ignored, the equation becomes for the liquid and the gas, respectively:

$$\varepsilon_l \rho_l U_l = Cst = \rho_l \frac{Q_l}{S} = \rho_l j_l \qquad \text{(Eq. 4)}$$

$$\varepsilon_g \rho_g U_g = Cst = \rho_g \frac{Q_g}{S} = \rho_g j_g \qquad \text{(Eq. 5)}$$

214 where Q_k and j_K are the flow rate and the superficial velocity (m/s), respectively, of phase k.

215 If it is considered that there is no liquid flow ($j_l= 0$, as in a batch bubble column), only the equation

216 for the gas phase remains and the previous equation becomes:

$$\varepsilon_g = \frac{j_g}{U_g} \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{(Eq. 6)}$$

217   since the sum of the different phase volume fractions is equal to unity:

$$\varepsilon_l = 1 - \varepsilon_g \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{(Eq. 7)}$$

218

219   2.2.2.2 Gas velocity equation: the Zuber and Findlay drift flux model

220   Zuber and Findlay (1965) proposed the following interfacial momentum transfer model:

$$U_g = C_0\, j + G = C_0\big(j_g + j_l\big) + G \qquad\qquad\qquad\qquad\qquad \text{(Eq. 8)}$$

221   Gas velocity (U_g) has two components, the first one corresponds to the gas transport resulting from

222   mixing (induced by mixture velocity j composed of gas and liquid superficial velocity, j_g and j_l

223   respectively) and the second one is gas slip velocity G, which corresponds to gas transport due to

224   buoyancy. The latter will be further developed below. The drift-flux coefficient (C_0) is related to the

225   non-uniformity of the gas-liquid flow field in the cross section and can be estimated from

226   computational fluid dynamics (CFD) simulations, as in Talvy et al. (2005). However in the case of a

227   homogeneous flow it can be considered close to 1. On the other hand, its extreme value would be

228   1.5 in the case of a spatially heterogeneous bubbly flow (Talvy et al. 2005).

229   With a homogeneous flow (C_0 = 1) and without the liquid flow rate (j_L = 0), the previous equation

230   becomes:

$$U_g = j_g + G \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \text{(Eq. 9)}$$

231   For homogeneous bubble columns at a low gas flow rate, j_g << G and then the gas velocity U_g is finally

232   assumed equal to the bubble slip velocity G.

233   Note that when the drift flux coefficient C_0 is equal to 1, radial gas fraction profiles are not considered

234   and thus radial interfacial forces as lift and turbulent dispersion are neglected for the axial resolution

235   (Talvy et *al.*, 2007a, b).

236

237 2.2.2.3 Gas slip velocity equation

238 A force balance applied to a rising gas bubble in a quiescent liquid and at steady state where the

239 bubble has reached its terminal rising velocity consists in equilibrium between buoyancy and drag

240 forces. The added mass force can be neglected in 1D models after a very short distance from the

241 bubble sparger, when the fully developed gas velocity is established (Talvy et *al.*, 2007a, Colombet et

242 *al.*, 2013).Thus, after simplification, the slip velocity G between the two phases can be calculated

243 using Eq. 10 (Talvy et al. 2007b):

$$G = \sqrt{\frac{4}{3} \frac{d_v^3}{d_p^2} \frac{(\rho_l - \rho_g)}{\rho_l} \frac{g}{C_D}} \qquad \text{(Eq. 10)}$$

244 with g the gravity constant (9.81 m/s^2), d_v the volume equivalent bubble diameter (m), C_D the drag

245 coefficient (-), and d_p the surface equivalent bubble diameter (m).

246

247 Furthermore, if the two equivalent diameters are considered equals ($d_v = d_p = d_B$, for a spherical

248 bubble, for example) and if gas density is ignored in comparison with liquid density, the following

249 simplified equation is obtained:

$$G = \sqrt{\frac{4}{3} d_B \frac{g}{C_D}} \qquad \text{(Eq. 11)}$$

250

251 2.2.2.4 Drag coefficient equation

252 Several correlations to calculate the drag coefficient exist in the literature, mostly expressed through

253 dimensionless numbers. In the case of a single rigid particle, the following law involving the Reynolds

254 number can be applied (Schiller and Naumann 1938):

$$C_D = \begin{cases} \dfrac{24}{Re} * (1 + 0.15\, Re^{0.687})\ for\ Re < 1000 \\ \qquad 0.44\ for\ Re > 1000 \end{cases} \qquad \text{(Eq. 12)}$$

255   However, even though this correlation is often used for rigid spherical bubbles, it is not suitable for

256   oblate ellipsoidal bubbles where the eccentricity effect drastically affects the drag coefficient (Talvy

257   et al. 2007b).

258   With ellipsoidal bubbles, when the surface tension effects are significant, drag laws based on the

259   Eötvös number are more relevant (Tomiyama et al. 1998, Dijkhuizen et al. 2010). The Eötvös number

260   (Eo), the ratio of buoyancy to surface tension, is defined as follows:

$$Eo = \frac{\left(\rho_l - \rho_g\right) g \, d_B{}^2}{\sigma} \qquad \text{(Eq. 13)}$$

261   where d_B is the bubble diameter (m) and σ is the liquid surface tension (N/m).

262

263   To analyze the impact of the effects of contamination on hydrodynamics, two drag laws depending

264   on the Eötvös number were selected. On one hand, the drag law proposed by Dijkhuizen et al.

265   (2010), developed using direct numerical simulation (DNS) and without contamination effects, is

266   considered as representative of a perfectly clean bubble surface (Eq. 14).

$$C_{D0} = \frac{8}{3} \frac{Eo}{\frac{19}{3} + \frac{2}{3} Eo} \qquad \text{(Eq. 14)}$$

267   On the other hand, the drag law proposed by Tomiyama et al. (1998), based on experimental results,

268   is considered as representative of classical experimental conditions with a slightly contaminated

269   system (Eq. 15).

$$C_D = max\left\{min\left\{\frac{24}{Re}(1 + 0.15Re^{0.687}), \frac{72}{Re}\right\}, \frac{8}{3}\frac{Eo}{(4 + Eo)}\right\} \qquad \text{(Eq. 15)}$$

270   These drag laws are based on single bubbles rising in liquid. For bubble swarms, a corrective factor,

271   depending on gas hold-up, can be taken into account to consider a hindered slipping gas velocity

272   (Eq.16; Wallis 1961):

$$C_D = C_{D0} \left(1 - \varepsilon_g\right)^{-2} \qquad \text{(Eq. 16)}$$

273

274   2.2.2.5 Hydrostatic pressure equation and impact on gas superficial velocity and bubble diameter

275   Hydrostatic pressure at a height z in a deep bubble column is given by Eq. 17.

$$P(z) = P_0 + \rho_m \, g \, (H - z) \qquad \text{(Eq. 17)}$$

276   where P_0 is the atmospheric pressure (Pa), g the gravity constant (m/s²), H the column height (m),

277   and ρ_m the mix density (or apparent density), defined as:

$$\rho_m = \rho_l \left(1 - \varepsilon_g\right) + \rho_g \varepsilon_g \qquad \text{(Eq. 18)}$$

278   Where ρ_l and ρ_g are the liquid and gas densities, respectively (kg/m³).

279

280   Moreover, bubble diameter evolves with pressure according to the following equation (Pöpel and

281   Wagner 1994; Fayolle et al. 2010), derived from the ideal gas equation when the mass transfer can

282   be ignored in the mass balance (Eq. 19):

$$d_B = d_{B0} \sqrt[3]{\frac{P_0}{P}} \qquad \text{(Eq. 19)}$$

283   where d_{B0} is the bubble diameter at atmospheric pressure P_0 (m), and d_B the bubble diameter at

284   pressure P(z). The bubble diameter at atmospheric pressure is an input datum that must be

285   measured or estimated since it depends on the gas sparger and water properties.

286

287   Gas superficial velocity j_{g0} at atmospheric pressure P_0 and superficial gas velocity j_g at pressure P(z)

288   are bound through the following equation, which is also derived from the ideal gas equation:

$$j_g(z) = j_{g0} * \frac{P_0}{P(z)} \qquad \text{(Eq. 20)}$$

289

290   2.2.3. Mass transfer calculation

291   Even though the hydrodynamic phenomena can be considered to reach a steady state, mass transfer

292   is fundamentally a transient phenomenon, using as input the hydrodynamic variables previously

293   calculated (gas hold-up, gas velocity, pressure, and bubble diameter along the column height). To

294   simulate oxygenation dynamics measured via reaeration tests (see 3.2), species transport equations

295   are presented for oxygen in a two-phase flow as in Talvy et al. (2007a) and further modified in order

296   to integrate the pressure effect for deep bubble columns.

297   When considering a perfectly mixed liquid without a liquid flow rate (batch bubble column), the

298   oxygen concentration equation in the liquid is written as follows for a 1-D system:

$$\frac{\partial C_l(t)}{\partial t} = \; < \frac{k_L a(z)}{1 - \varepsilon_g(z)} \, (C_l^*(z,t) - C_l(t)) >$$
(Eq. 21)

$$C_l^*(z,t) = \; He_{O2}(T) \, M(O_2) \, x_g(z,t) \, P(z)$$
(Eq. 22)

299   The oxygen concentration in the liquid (C_l) is expressed as a mass concentration and C_l^* is the

300   saturation concentration at equilibrium. The variation of oxygen concentration in the liquid phase

301   over time results from a transfer term from the gas to the liquid. The parameters $k_L a$ and ε_g are the

302   mass transfer coefficient and gas hold-up, respectively, $He_{O2}(T)$ the Henry law coefficient at

303   temperature T for oxygen solubility in water (1.24×10^{-5} mol/m^3/Pa at 25°C), $M(O_2)$ the oxygen molar

304   mass (32 g/mol), $x_g(z)$ the local oxygen molar fraction in the gas phase at height z and P(z) the local

305   hydrostatic pressure.

306

307   Because of the perfectly mixed liquid assumption, only one equation for the whole liquid volume is

308   considered, and the parameters $k_L a$, ε_g and C_l are taken as their average value in the column for the

309   calculation. The oxygen concentration in the gas phase $C_g(z)$ can be calculated by the ideal gas

310   equation from the oxygen molar fraction $x_g(z)$. As for the liquid, the oxygen concentration in the gas

311   phase changes over time, although it is difficult to measure.

312   Thus, for low soluble gases, the 1-D transfer equation in the gas phase gives (Talvy et al., 2007):

$$\frac{\partial \varepsilon_g C_g(z,t)}{\partial t} + \nabla \, \varepsilon_g(z) C_g(z,t) U_g(z) = \; -k_L a(z)(C_l^*(z,t) - C_l(t))$$
(Eq. 23)

313   The first term on the left side corresponds to the evolution over time and the height of the oxygen

314   concentration in the gas phase, the second to the transport term of oxygen by the gas velocity and

315   the term on the right side is the oxygen transfer term from the gas to the liquid. In the gas phase,

316   neither diffusion nor reaction is considered, since the model applies for homogeneously dispersed

317   bubbly flow where no coalescence between bubbles occurs.

318   When solving the equation of the oxygen molar fraction in the gas phase, it gives an expression with

319   a first order discretization for the gas phase convective transport:

$$\frac{\partial x_g(z,t)}{\partial t} = -\frac{k_L a(z)}{\varepsilon_g(z) * \frac{M(O_2)}{RT}\left(P(z) - P_{vap}\right)}\left(C_l^*(z,t) - C_l(t)\right) - \frac{U_g(z)}{\Delta z}\Delta C_g(z,t) \qquad\qquad \text{(Eq. 24)}$$

320   where $k_L a(z)$ is the local mass transfer coefficient, R the ideal gas constant (8.314 J/mol/K), and $U_g(z)$

321   the local bubble velocity. The gas concentration variation over time therefore results from a negative

322   transfer term from the gas to the liquid, and from a transport term related to the gas phase velocity.

323   Equation 24 is solved for each z-position in the column following the z-axis: the oxygen molar fraction

324   in the gas $x_g(z)$ is then calculated for each height over time with the local hydrodynamic parameters

325   solved from the equations provided in section 2.2.2. In this model, the hydrodynamic parameters

326   have a local impact on local mass transfer, but the reverse is not considered given that the oxygen

327   depletion in the gas phase can be ignored for the gas flow rate (Talvy et al. 2007a, Baeten et al.

328   2020).

329

330   2.2.4. Models for mass transfer coefficients

331   The mass transfer coefficient $k_L a$ could be expressed in terms of the interfacial area a and the liquid-

332   side mass transfer velocity k_L (m/s). To estimate the latter, there are several existing models and, as

333   for the drag coefficient, they depend on whether or not the bubble interface is contaminated (Dani

334   et al. 2007, Xu et al. 2018).

335   On one hand, the Higbie model is very commonly used and corresponds to the ideal case of perfectly

336   clean (non-contaminated) bubbles, which have a renewable interface: the diffusional oxygen transfer

337   in the liquid film surrounding gas bubbles occurs when the liquid elements reach the gas-liquid

338   interface and during a short contact time (t_c) they attain the concentration equilibrium with the

339   interface. Under these conditions, the mass transfer coefficient is written as (Higbie 1935):

$$k_L = 2 \sqrt{\frac{D}{\pi \, t_c}} = 2 \sqrt{\frac{D \, G}{\pi \, d_B}} \qquad \text{(Eq. 25)}$$

340   where k_L is the liquid side mass transfer coefficient (m/s), D the diffusion coefficient of oxygen in

341   water (m²/s), t_c the contact time (s), G the gas slip velocity (m/s) and d_B the bubble diameter (m).

342   On the other hand, the case of completely contaminated bubbles is described by the Frössling model,

343   which assumes that bubbles have a rigid, non-renewable interface. The mass transfer coefficient is

344   then expressed as (Frössling 1938):

$$k_L = \frac{D}{d_B} * (2 + 0.6 * Re^{0.5} * Sc^{0.33}) \qquad \text{(Eq. 26)}$$

345   where the Reynolds and Schmidt dimensionless numbers are defined as:

$$Re = \frac{\rho_l \, d_B \, G}{\mu_l} \qquad \text{(Eq. 27)}$$

$$Sc = \frac{\mu_l}{\rho_l \, D} \qquad \text{(Eq. 28)}$$

346   where ρ_l and μ_l are respectively density (kg/m³) and the dynamic viscosity (Pa.s) of the liquid.

347

348   In practice, the k_L coefficients calculated with the Frössling correlation are much lower than with the

349   Higbie model, i.e., that bubbles are contaminated and thus mass transfer is hindered due to the

350   impurity molecules (e.g., surfactants) adsorbed at the bubble surface. The k_L coefficients measured

351   are thus always between these two asymptotic and ideal cases (Xu et al. 2018).

352

353   2.2.5 Volumetric bubble interfacial area a

354   The interfacial area of spherical bubbles is given by (Eq. 29):

$$a = \frac{6}{d_B} \varepsilon_g \qquad \text{(Eq. 29)}$$

355   where a is the bubble's interfacial area (m^2/m^3), d_B the bubble's diameter (m), and ε_g the gas hold-up

356   (-).

357   If the bubbles are ellipsoidal, a correction factor that includes bubble eccentricity K (the ratio of

358   major axis to minor axis) is taken into account (Cockx et al. 1997, Colombet et al. 2011):

$$a = \frac{6}{d_B} \, \varepsilon_g \, f(K) \qquad \text{(Eq. 30)}$$

$$f(K) = \frac{1}{2 \, K^{1/3}} * (K + \frac{\ln(K + \sqrt{K^2 - 1})}{\sqrt{K^2 - 1}}) \qquad \text{(Eq. 31)}$$

359   Ellipsoidal bubbles have a higher interfacial area than spherical ones, thus f(K) is always higher than

360   1.

361

362   2.2.6 Numerical method, boundary and initial conditions.

363   First, the 1D steady state model runs using Matlab® for a fully developed bubbly flow (equations 5 to

364   20 with the algebraic solver function fsolve) in order to obtain axial profiles of the gas fraction, the

365   gas velocity, the pressure and the bubble diameter along the column height (50 layers along z) as a

366   function of the input parameters (inlet bubble diameter, gas flow rate, column height). Then, mass

367   transfer between the gas and the liquid phase are calculated from hydrodynamics results with a

368   transient solver (ode23t function for equations 21 to 24 with closure relations 25 to 31). This one-

369   way coupling hydrodynamics and mass transfer is only valid with the assumptions that the mass

370   transfer does not modify hydrodynamic parameters (i.e. similar molar flow rates in the gas phase).

371   For all the simulations presented hereafter, the initial molar fraction of oxygen in the gas was set to

372   the inlet atmospheric condition at the bottom of the column (xg(z) = 0.21) for all discretization layers

373   along column height, physically corresponding to the fact that fresh air is continuously supplied in

374   the column from the bottom, so that the oxygen molar concentration in the gas at the inlet does not

375   vary. The initial dissolved concentration in the liquid phase was considered as an initial condition:

376   depending on the simulated experiments, its value was set to the initial experimental dissolved

377   oxygen concentration (mostly equal to zero). Finally, the simulated length of time is also adjustable,

378 and it has to be long enough to allow the system to reach an equilibrium state, i.e. when the oxygen

379 concentration in liquid is equal to the saturation value. The time to reach steady state conditions

380 depends on the mass transfer from bubbles and on experimental conditions. For the bubble columns

381 considered, the simulated time period lies between 500 and 20,000 s.

382

383 **3. Results and discussion**

384 3.1 Hydrodynamic characterization of the datasets studied

385 A pragmatic approach is applied to select the combinations of correlations and closure laws that

386 make it possible to obtain a reliable description of the three experimental datasets with the 1-D

387 model, in terms of global gas hold-up changes with the superficial gas velocity. The combinations of

388 the closure laws considered are presented in Table 3.

389

390 **Table 3.** Selected combinations of closure laws for appropriated modelling of each datasets.

Dataset	Pressure effects on bubble size and gas superficial velocity	Contamination effects regarding hydrodynamics (via the drag law considered)	Collective effects (via Eq. 16)
D1	Included	Contaminated (Tomiyama drag law)	Included
D2	Included	Contaminated (Tomiyama drag law)	Included
D3	Included	No contamination (Dijkhuizen drag law)	Included

391

392 The selected model structures include pressure and collective effects for all datasets. The drag law

393 correlation of Tomiyama et al. (1998) is used for the datasets obtained with unfiltered tap water (D1

394 and D2), whereas the correlation proposed by Dijkhuizen et al. (2010) is used to simulate the

395 hydrodynamics for the dataset obtained with filtered tap water (D3). For each dataset, the model

396 including the closure laws presented in Table 3 is called the "base model" in the following.

397 Figure 3 presents the simulated and experimental gas hold-up as a function of the superficial gas
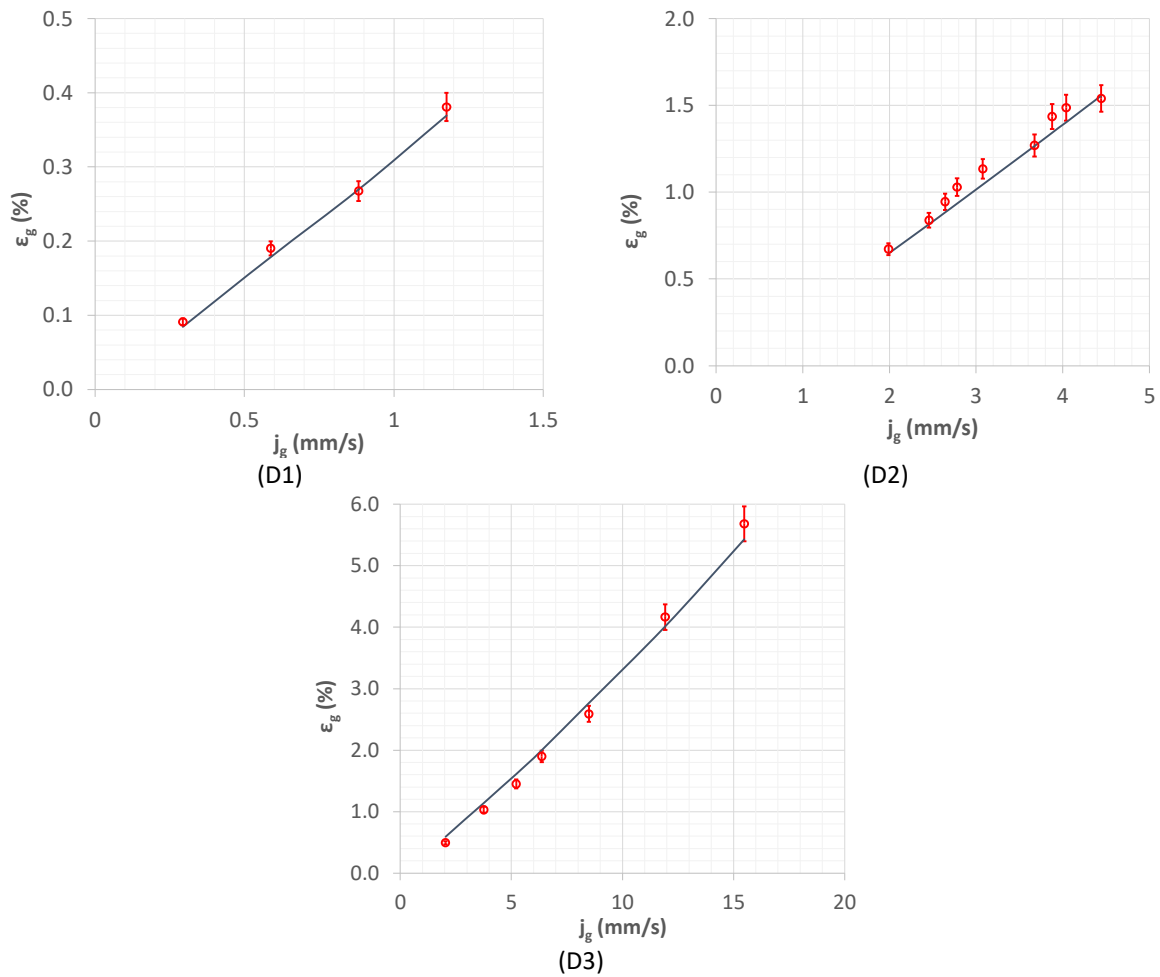

398 velocity.

Figure 3. Global gas hold-up for different superficial gas velocities and for each dataset − Base models (**O**: Experimental data / ——: Base model / Error bars: ± 5%)

399

400   Good accuracy is obtained comparing simulated and experimental values (with an average difference

401   between the experimental and simulated values of 4.6, 5.1 and 8.0 % for D1, D2 and D3 respectively).

402   These results highlight that the 1-D model, considering appropriate closure laws, is relevant to model

403   steady-state hydrodynamics of the bubble column along the vertical direction. The model is used in

404   the following section in order to analyze the impact of selected closure laws and physics and to

405   propose a deeper analysis of the different datasets on the basis of the effects considered (pressure,

406   contamination effects and collective effects). The impact of the effects considered is analyzed per

407   dataset by modifying the associated closure law in the model presented in Table 3.

408

409   *3.1.1. Analysis of the pressure impact on hydrodynamics*

410   The pressure effects on hydrodynamics is integrated into the model via bubble diameter (Eq. 19) and

411   gas superficial velocity (Eq. 20), in order to take into account gas volume expansion (and associated

412   bubble size) with variation in the local hydrostatic pressure. Since the mean bubble diameter varies

413   with pressure following a cubic root law, the impact of pressure on this parameter is not as high as

414   for gas superficial velocity.

415   Figure 4 presents the changes in the overall hold-up as a function of the superficial gas velocity for

416   the modified model (i.e. without considering the pressure effect on bubble size and superficial gas

417   velocity along z), the base model (Table 3) and the experimental data for each dataset.

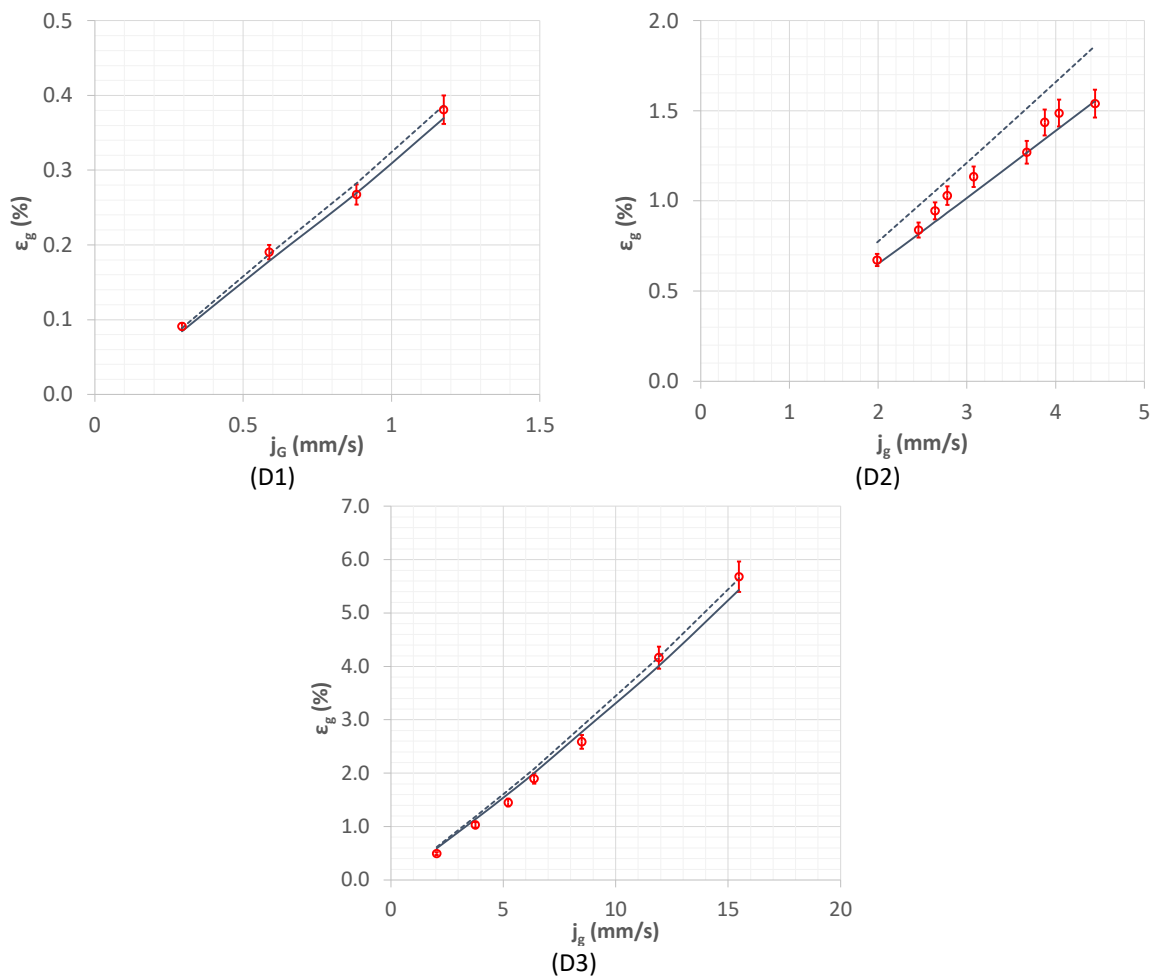

Figure 4. Overall gas hold-up for different superficial gas velocities and for each dataset. Impact of the pressure effects (O: Experimental data / ▬ : Base model (with pressure effects) / ▪▪▪▪ :Modified model (without pressure effects) / Error bars: ± 5%)

418

419   As expected, the deviation due to the pressure effects is the most significant for dataset D2, because

420   the water height is highest (4.5 m). The simulated gas hold-up is lower when the pressure effects are

421   considered (28 % of the overall gas hold-up overestimation when the pressure impact is not

422   accounted for), and experimental points are better described in that case. For datasets D1 and D3,

423   since the water height is low (1.3 and 0.8 m, respectively), the simulation results are less affected.

424   For deep bubble columns, the impact of hydrostatic pressure on the gas-liquid hydrodynamics (i.e. ε_g)

425   along the column height are significant mainly due to its influence on gas superficial velocity (and to

426   a lesser extent due to its influence on bubble size) and must be taken into account to appropriately

427   model gas hold-up. For low soluble gases and a bubble size between 3 and 5 mm, the slip velocity is

428   almost constant and the effect of local pressure on gas hold-up can be estimated considering a linear

429   correlation, deduced from the ideal gas law:

$$\frac{\varepsilon_g}{\varepsilon_{g0}} = \frac{1}{2}\left(1 + \frac{P}{P_0}\right) \approx 1 - \frac{\rho_m g H}{2P_0} \approx 1 - \frac{H}{20} \qquad \text{(Eq. 32)}$$

430   Using Eq. 32, the reduction of the overall gas hold-up over the column height can be roughly

431   estimated at 5% per meter (1/20).

432

433   *3.1.2. Analysis of contamination effects on hydrodynamics*

434   The impact of contamination effects is then analyzed via the drag law considered included in the

435   model.

436   Since the bubbles are ellipsoidal, drag laws applied to the three datasets are focused on correlations

437   depending on the Eötvös number (see Table 3). Since different water qualities could be considered in

438   regards to experimental conditions (clean water [filtered water] for D3 and contaminated water [tap

439   water] for D1 and D2), consistent drag correlations were selected to analyze their impact on

440   hydrodynamics. As indicated in section 2.2.2.4, Dijkhuizen's drag correlation was selected for clean

441   bubble surfaces, whereas Tomiyama's was considered for contaminated bubbles. Please note that

442   the base model for D3 included Dijkuizen's drag law, whereas the base model for D1 and D2 included

443   Tomiyama's drag law.

444   Figure 5 presents the overall hold-up as a function of the superficial gas velocity for models including

445   Dijkhuizen's or Tomiyama's drag correlations and the experimental data for each dataset. The other

446   closured laws considered in the respective models remain similar to Table 3.

Figure 5. Overall gas hold-up for different superficial gas velocities and for each dataset (**O**: Experimental

data / ▬ : Dijkhuizen's drag correlation / ▪▪▪▪ : Tomiyama's drag correlation / Error bars: ± 5%)

447   The gas hold-up modeled was significantly impacted by the modification of the drag law considered,

448   related to the contamination effects. The mean modeled values considering Tomiyama's drag

449   correlation are from 15 to 22 % higher in comparison with modelled results obtained with

450   Dijkhuizen's drag law, depending on the dataset considered and on the gas flow rate. The results

451   obtained with the model that included Dijkhuizen's drag law fit the experimental points of dataset D3

452   better. This is a reasonable result related to the water quality of this dataset, which could be

453   considered close to clear water (filtered water) and to the air diffuser (capillaries): the high air flow

454   rate applied induces a lower contact time between nascent bubbles and liquid during bubble

455   formation along the capillary (Loubière et al. 2003). In the case of datasets D1 and D2, the

456   experimental data are better described by the model integrating Tomiyama's drag correlation. This is

457   in accordance with the water quality during these experiments (tap water). Considering

458   hydrodynamics, the bubble surface for datasets D1 and D2 must be considered as contaminated,

459   whereas it must be considered as clean for dataset D3. These results highlight that drag laws must be

460   selected in accordance with actual operating conditions in order to consider bubble interface

461   contamination by real water.

462   Due to the narrow gas hold-up range in the datasets selected, the deviation in the simulation

463   hydrodynamics results related to the collective effects are less significant than for the effects

464   discussed above. The mean deviation is lower than 5%, with the highest values observed for dataset

465   D3 due to the wider range studied in terms of gas hold-up. From the model (using Eq. 16), we can

466   estimate, by limited development of Eq. 12, that the gas fraction increase is around 2% of relative

467   deviation per percentage of gas hold-up. Therefore, the collective effect cannot be ignored for gas

468   hold-up from 3% (deviation greater than 6%, the data are given in supplementary material – Figure

469   S1).

470

471   3.2 Mass transfer results

472   The simulated time variation of the dissolved oxygen concentration in liquid $C_l(t)$ allows one to

473   calculate an overall K_La coefficient for the entire bubble column (Cockx et al. 2001) through the

474   following classical equation:

$$C_l(t) = C_l^* - (C_l^* - C_{l0}) e^{-K_La*t}$$ (Eq. 33)

475   where C_{l0} is the dissolved oxygen concentration at t=0 (mg/L) and K_La is the overall mass transfer

476   coefficient (h^{-1}). For example, the experimental dissolved oxygen over time obtained by Duran et al.

477   (2016) was compared with simulated dissolved oxygen (cf. supplementary materials – Figure S2).

478   K_La is also called the apparent mass transfer coefficient, since it assumes a constant equilibrium

479   oxygen concentration C_l^*, although it actually varies with the oxygen concentration in gas during

480   reoxygenation (see Eq.22). Furthermore, the K_La coefficient is considered as a whole, with no

481   distinction between K_L and a. This overall apparent K_La coefficient differs from the local k_La

482   coefficient, which results from the multiplication of the local liquid-side mass transfer coefficient k_L

483   (for example modeled with the Higbie penetration model) and the local interfacial area *a*. This local

484     $k_L a$ coefficient varies locally essentially with z in a bubble column and can be averaged in the whole

485   liquid volume. Moreover, it is quite difficult to determine experimentally k_L and *a* separately in a real

486   bubble column (Colombet et al. 2011, 2015).

487   In the following section, global K_La values determined experimentally are compared with simulated

488   global K_La coefficients with the Higbie and Frössling models for k_L, in order to see which transfer

489   model fits the experimental points better when contamination of the bubbles is not fully controlled

490   (real water).

491

492   3.2.1 Comparison of the Higbie and Frössling transfer models

493   Figure 6 presents the overall K_La versus the superficial gas velocity for the three experimental

494   datasets and associated modelling results.

Figure 6. Overall K_La transfer coefficients for different superficial gas velocities and for datasets D1–D3 (**O**: Experimental data /——: Modelled global K_La with Higbie model / ——: Modelled global K_La with the Frössling model / Error bars: ±5%)

495

496   For dataset D3, the mass transfer is closer to the Higbie model (clean bubble surface) than to the

497   Frössling model (contaminated bubble surface). From the 1-D transient simulation, it can be deduced

498   that the transfer interface is slightly contaminated (bubble size between 2.3 and 3.4 mm) even if the

499   hydrodynamic simulation results show that filtered water does not reduce the bubble velocity

500   (apparent clean interface for the drag force).

501   For dataset D2, the water quality is lower (tap water) and consequently induces contamination of the

502   bubble surface, affecting the drag coefficient, which is confirmed by the hydrodynamics results (see

503   section 3.1.2). However, Figure 6 highlights that the overall mass transfer is not really impacted

504   because the transfer simulation shows that the non-contaminated Higbie model (clean bubbles)

505 works better than the Frössling model (fully contaminated bubbles). This apparent contradiction can

506 be explained by the fact that for dataset D2, the bubbles are larger and ellipsoidal, between 3 and 4

507 mm. In this case, the contaminants at the bubble interface are transported to the rear of the bubble

508 where local mass transfer is drastically lower than at the front where interface renewal is greater

509 (Dani et al. 2007, Figueroa and Legendre 2010). For this reason, the bubble slip velocity could be

510 reduced for large bubbles in tap water as observed in Figure 5, but not the mass transfer velocity

511 (Figure 6).

512 For dataset D1, experimental K_La values are much lower compared to D2 and D3 and seem slightly

513 closer to the Frössling model. This can be related to the fact that bubbles in these experiments are

514 significantly smaller and spherical (below 1.8 mm) and more likely to be contaminated, with a more

515 rigid and less renewable bubble interface. In this case, the slip velocity behaves like a completely

516 contaminated bubble and the mass transfer velocity is clearly lower than for larger bubbles also with

517 tap water (as observed for dataset D2).

518 These results confirm that when tap water is used, the Higbie transfer model is the most accurate for

519 large bubbles (dataset D2, bubble size, 3.0–4.0 mm) and less relevant for small ones (dataset D1,

520 bubble size, 1.5–1.8 mm), with significant contamination effects. For filtered water, the Higbie model

521 is also the most suitable, although the presence of small contaminants could have slightly reduced

522 the mass transfer velocity for intermediate bubble size (2.3–3.4 mm) because the water could not be

523 considered as really pure (Colombet et al. 2015) except when rigorous experimental conditions are

524 maintained with ultra-pure water. A complementary discussion on transfer contamination is detailed

525 in section 3.2.3 after analysis of the depletion effect which can imply bias in transfer velocity

526 estimation.

527

528 3.2.2 Comparison of mean local k_La and overall K_La: the oxygen depletion effect

529 In the previous discussion, the apparent K_La is compared to the simulation results with two

530 asymptotic models for clean bubble interfaces (Higbie model) and fully contaminated ones (Frössling

531   model). During this comparison, the pressure effect on the gas fraction, the bubble diameter and the

532   oxygen saturation was modeled to take into account all the relevant physical phenomena that

533   modify hydrodynamic and mass transfer parameters. With the "base model" (Table 3), it is also

534   possible to clarify the effect of pressure and height on the mass transfer. In Figure 8, experimental

535   overall K_La values are compared to both simulated overall K_La coefficients and to mean local values

536   (spatial average $<k_La>$) calculated using the Higbie transfer model for simplicity.

(D1)

(D2)

(D3)

Figure 7. Experimental and modeled overall K_La and mean local $<k_La>$ for different superficial gas velocities

and for datasets D1–D3 (**O** : Experimental global K_La / ▬ : Simulated global K_La with the Higbie model /∙∙∙∙ :

Simulated spatial average $<k_La>$ with the Higbie model / Error bars: ±5%)

537

538   The simulated global K_La coefficients are systematically lower than the simulated mean local $<k_La>$

539   coefficients, the difference stemming from the oxygen depletion in the gas (due to the column

540   height) and thus a decrease of the equilibrium concentration C_l^* (Eq.24). Simulated global K_La

541   coefficients describe the experimental points more accurately since this parameter is deduced from

542   reoxygenation curves versus time as for the experimental data, especially for dataset D2. Indeed,

543   oxygen depletion in the gas is significant due to the high column height (4.5 m of water). For the

544   other datasets, given the high superficial gas velocity and the low column height in the case of D3

545   (0.76 m), the difference between mean local and global K_La is the least significant. Surprisingly for

546   dataset D1, since the column height is relatively low (1.3 m) and the superficial gas velocity is very

547   low, the difference between the two K_La coefficients modeled is also relatively substantial (mean

548   difference, 55%)

549   To understand and model this depletion effect in the gas, a simplified analysis is proposed in the

550   following section.

551

552   3.2.3. When mean local $<k_La>$ differs from overall K_La: modeling the depletion effect

553   The following development aims at explaining more deeply the effect of superficial gas velocity,

554   column height and other process parameters on oxygen depletion. Compared to the mass transfer

555   time ($1/K_La$), the bubble convection time or residence times (H/U_g) are smaller. The convection time

556   and mass transfer time values are provided in the supplementary materials for the three datasets

557   (Table S1).

558   Moreover, oxygen depletion in the gas occurs essentially at the beginning of the reoxygenation

559   process, during a transient period (t << $1/K_La$) when the oxygen concentration in the liquid $C_l(t)$ is

560   close to 0 mg/L. During this transient period, Eq. 23 becomes:

$$\nabla \varepsilon_g C_g(z) U_g = -k_L a (C_l^*(z) - 0) \qquad \text{(Eq. 34)}$$

561   It appears that the depletion in the gas is given by the mass transferred. By estimating the oxygen

562   saturation with the Henry' law (Eq. 22) and the interfacial area (Eq. 29), with the exchange coefficient

563   m (Talvy, 2007), Eq. 34 becomes:

$$\nabla \varepsilon_g C_g(z) U_g = -k_L \frac{6. \, \varepsilon_g}{d_B} . m . C_g(z) \qquad \text{(Eq. 35)}$$

564   with $m = He_{O2}.RT.$

565   Assuming that the gas velocity is kept constant along the height of the bubble column, the

566   integration gives the following variation in the concentration along z:

$$\varepsilon_g C_g(z) = \varepsilon_{g0} C_{g0}.e^{-k_L\frac{6}{d_B}.m.\frac{z}{U_g}} \qquad \text{(Eq. 36)}$$

567   The depletion in the gas (C_g/C_{g0}) decreases exponentially with (i) the mass transfer velocity k_L, (ii) the

568   solubility m (iii) the distance from the diffuser z, and (iv) the inverse of bubble size and the associated

569   slip velocity.

570   In this equation, $\varepsilon_g C_g$ is the mass of soluble gas per unit of volume (m_g) by introducing a depletion

571   factor (DF) for the whole column as:

$$DF = k_L\frac{6}{d_B}.m.\frac{H}{U_g} \qquad \text{(Eq. 38)}$$

572   It is possible to estimate the decreasing ratio of mass in the gas along the height the bubble column

573   using Eq. 39:

$$\frac{m_g}{m_{g0}} = \frac{\varepsilon_g C_g}{\varepsilon_{g0} C_{g0}} = e^{-DF.\frac{z}{H}} \qquad \text{(Eq. 39)}$$

574

575   For example, the depletion factor for D1 and D2 are close to 0.3 and 0.4, respectively, which

576   corresponds to depletion loss in the gas of 26% and 33 % using Eq. 38 at the top of the bubble

577   column. For dataset D3, the depletion factor is close to 0.05 and the decrease in the oxygen molar

578   fraction in the gas is lower than 5%. In our study, as the solubility is constant and the mass transfer

579   velocity k_L is quite constant for millimetric bubbles for oxygen, the substantial variation in the

580   depletion factor is mainly related to the length ratio H/d_b, which is about 800, 1200 and 200 for

581   datasets D1,D2 and D3, respectively. To illustrate the accuracy of the depletion model (Eq. 39), Figure

582   10 presents the oxygen molar fraction in the gas as a function of the distance from the diffusers at

583   the initial time (t=0) and in the stationary state (t>>1/ K_La) for D1 and D2 when the depletion effect is

584   significant (Figure 7).

30

(i – D1)　　　　　　　　　　　　　　　　(i – D2)
585　**Figure 10.** x_g as a function of z (distance from the diffuser) – Modelled for C_l = 0 mg/L (●) / Depletion law for C_l

586　= 0 mg/L (——)/ Modelled (○) for Cl = Cl* - j_g = 1.2 and 4.4 mm/s for D1 and D2 respectively

587

588　The oxygen depletion estimated with the relation (Eq. 39) is in good accordance with the

589　comprehensive 1D model. The depletion factor (Eq. 38) can then be used to identify the

590　experimental conditions inducing a significant impact of the gas depletion effects on the global mass

591　transfer coefficient K_La.

592　This depletion effect is clearly increased by (i) a long bubble residence time (H/U_g=4.3 s and 18.3 s for

593　D1 and D2, respectively), (ii) the high solubility of the gas considered passing into the liquid phase

594　(here m = 0.0034 is relatively low for oxygen in water) and (iii) the low transfer time at the bubble

595　scale (d_B/k_L=2.8 s and 9.4 s for D1 and D2, respectively).

596　In comparison with the relative simplicity of the estimation of the mean bubble residence time (H/U_g)

597　in a bubble column, it is much more difficult to determine the bubble transfer time (d_B/k_L) precisely,

598　which can vary along the column height due to substantial bubble size changes with increasing

599　hydrostatic pressure. However, this bubble transfer time could be estimated through the inverse

600　ratio of the global volumetric transfer coefficient to the global gas fraction (K_La/ε_g). This last

601　parameter is also close to the transfer number N_T (Figure 2) but both approximations imply a certain

602　bias because all the nonlinearity effects on average values are ignored.

603

604   3.2.4 Mass transfer and bubble contamination angle

605   In this section, the level of bubble contamination is studied through their contamination angle,

606   according to the theory developed by Sadhal and Johnson (1983). The level of bubble contamination

607   is characterized through a contamination angle, corresponding to the contaminated interface

608   occupied by the adsorbed contaminants at the bubble surface, expressed as the angle between the

609   rear of the bubble and the limit of the contaminated surface. The contamination angle varies

610   between 0° and 180°, depending on whether the bubble surface is completely clean or completely

611   contaminated, respectively. For all experimental data, the experimental global $K_L a$ coefficients lie

612   between the ideal $K_L a$ coefficients obtained with the Higbie and Frössling mass transfer models

613   (Figure 6). The contamination angle is obtained from the dimensionless drag coefficient with the

614   following correlation (Sadhal and Johnson 1983; Dani 2007):

$$C_D^*(\theta_{cap}) = \frac{1}{2\pi}\left(2\theta_{cap} + \sin(\theta_{cap}) - \sin(2\theta_{cap}) - \frac{1}{3}\sin(3\theta_{cap})\right) \qquad \text{(Eq. 38)}$$

615   with θ_{cap} the drag contamination stagnant cap angle (in radian).

616   On the other hand, the dimensionless drag coefficient $C_D^*(\theta_{cap})$ is related to the Sherwood numbers

617   of the bubble (experimental), of a completely clean bubble (Higbie correlation) and of a completely

618   contaminated bubble (Frössling correlation) as follows (Takemura and Yabe 1999, Dani 2007, Xu et

619   al. 2018):

$$C_D^*(\theta_{cap}) = 1 - \left(1 - \frac{Sh - Sh_{Higbie}}{Sh_{Frössling} - Sh_{Higbie}}\right)^2 \qquad \text{(Eq. 39)}$$

620   with Sh the experimental Sherwood number, Sh_{Higbie} the Sherwood number of a completely clean

621   bubble and $Sh_{Frössling}$ the Sherwood number of a completely contaminated bubble.

622

623   The Sherwood number is defined as follows:

$$Sh = \frac{k_L * d_B}{D} \qquad \text{(Eq. 40)}$$

32

624   with k_L the experimental mass transfer velocity estimated from the experimental reoxygenation

625   curves using the 1-D model (via iterative calculation).

626

627   Table 4 presents the Sherwood numbers of the real bubbles calculated from the comprehensive

628   model of a completely clean and a completely contaminated equivalent bubble. The transfer

629   contamination angle is then deduced from Eq. 38 for datasets D1 and D3.

630   **Table 4.** Sherwood numbers and contamination angle and for the experimental dataset D1 and D3

Dataset	j_g expressed at P_{atm} (mm/s)	d_b expressed at P_{atm} ($\times 10^{-3}$ m)	k_L ($\times 10^{-4}$ m/s)	Sh_{exp} (-)	Sh_{Higbie} (-)	$Sh_{Frössling}$ (-)	Θ_{cap} (°)
D1	0.29	1.48	3.80	313	625	120	105
	0.59	1.69	3.47	286	568	109	105
	0.88	1.71	3.01	248	562	108	113

	14.26	3.28	3.47	569	749	147	73

631

632   For each dataset, the contamination angles vary slightly with superficial gas velocity and the water

633   quality appears to be specific for each dataset.

634   For dataset D1, the transfer contamination angle lies between 105 and 113°, which indicates a high

635   level of bubble contamination that substantially reduces the mass transfer compared to an

636   equivalent clean bubble (around 50%). This angle designation is consistent with the fact that the

637   experimental hydrodynamics (i.e. ε_g) of dataset D1 was adequately reproduced using a drag

638   coefficient set for contaminated bubbles (Figure 5).

639   For dataset D3, lower transfer contamination angle values were obtained in comparison with dataset

640   D1. Even if the water is very clean (filtered tap water), the mass transfer is still hindered compared to

641   a clean equivalent bubble (between 24 and 36%), but the decrease of the drag coefficient due to the

642   water contamination remains negligible (Figure 5).

643 For dataset D2, since experimental global K_La values fit well with the Higbie model (see Figure 6), it

644 can be deduced that bubbles have transfer contamination angles close to zero and are equivalent to

645 completely clean bubbles. This means that the greater the bubble size, the less the drag

646 contamination impact has an effect on mass transfer:1.5-, 2.5- and 3.5-mm bubbles correspond to

647 105°, 88° and 0° contamination angles, respectively. This means that when the bubble size increases,

648 it becomes ellipsoidal and the mass transfer occurs intensively at the front of the bubble where the

649 transfer contamination tends to become negligible (Dani et al., 2021).

650

651 3.2.5 Discussion on mass transfer modeling

652 Hydrodynamic parameters calculated with the 1D model in steady state conditions (bubble

653 diameters, gas hold-up and gas velocity) were validated and then used in order to calculate

654 reoxygenation and global K_La mass transfer coefficients. A distinction was made between mean local

655 $<k_La>$ and apparent global K_La. The latter is calculated from simulated curves of dissolved oxygen

656 concentration over time, and takes into account oxygen depletion in the gas phase and therefore the

657 variation in the equilibrium concentration versus time. A comparison with the experimental data of

658 global K_La therefore provides accurate results, especially for deep bubble columns and/or a low gas

659 flowrate when oxygen depletion in the gas increases (Eq. 36). The depletion factor (Eq. 37) is adapted

660 to characterize and interpret situations where the effects of oxygen depletion influence the gas–

661 liquid transfer due to gradient in the gas phase composition.

662 Moreover, for the three experimental datasets, the Higbie and Frössling mass transfer models were

663 used to interpret mass transfer results with no bias related to the quality of the liquid phase

664 composition (Baeten et al. 2020). When tap water was used for experiments (D1 and D2), the smaller

665 the bubbles, the more they were contaminated. Consequently, the global mass transfer coefficient

666 could be drastically reduced (up to 50% by model comparison with clean bubbles with dataset D1).

667 Surprisingly, even if contamination reduces the slip velocity in dataset D2, mass transfer is not

668 affected by the contamination because the bubbles are big enough to be ellipsoidal: in this case the

669   transfer occurs mainly at the front of the bubble interface (Dani et al. 2006). For dataset D3 obtained

670   using filtered water, the mean slip velocity of bubbles corresponds to that obtained for pure water.

671   However, for this relatively clean water, the bubble surface was still characterized as partially

672   contaminated (contamination angle estimated at 100°).

673   In the context of oxygen transfer in aeration processes, it is then possible to ignore the effect of

674   contamination with tap water for ellipsoidal bubbles greater than 3 mm (as for dataset D2).

675   However, for small bubble sizes (under 2 mm), the quality of the tap water can drastically reduce the

676   mass transfer (more than 50% compared to clean bubbles). In both situations, depletion effects are

677   substantial in deep bubble columns but must also be taken into account for relatively low column

678   height and specific studies (low mean bubble size or high solubility of the component studied).

679   In addition, the impact of eccentricity on the modeled mass transfer coefficient is given in

680   supplementary information (Figure S3). For datasets D2 and D3, the mean local $<k_La>$ values modeled

681   are slightly higher when eccentricity is taken into account. To remain physically consistent,

682   eccentricity must be systematically considered to calculate the interfacial area of ellipsoïdal bubbles.

683

684   **4. Conclusions**

685   The main conclusions of this study are:

686   • The proposed 1-D model is able to reproduce experimental hydrodynamic (global gas hold-

687   up) for three different experimental datasets in bubble columns with an air/clear water

688   system. The closure laws considered must be rigorously selected in order to integrate the

689   impact of contamination, collective and pressure effects on hydrodynamics, and the mass

690   transfer parameters. Depending on the experimental water height, hydrostatic pressure

691   influences on the hydrodynamic parameters plays a major role and must be considered in

692   the model (an approximately 5% decrease on gas hold-up per meter of depth). The

693   importance of the drag law choice is also highlighted, depending on the water quality and its

694   influence on bubble contamination.

695   • The gas oxygen concentration significantly depletes due to the transfer to liquid and thus the

696   equilibrium concentration varies, which explains the difference between the mean local

697       $<k_La>$ and global K_La coefficients. This difference becomes substantial for high soluble gas

698   with high transfer rate and/or a high bubble column and/or low mean bubble size d_b. A

699   depletion factor is proposed in order to warn of situations in which the experimental

700   determination of the overall mass transfer coefficient must be conducted rigorously by

701   considering this depletion effect through an estimation from the reoxygenation curves. The

702   substantial impact of the depletion in the gas phase composition is drastically increasing with

703   the length ratio H/d_b.

704   • The suitability of the Higbie k_L model for clean water transfer modelling is demonstrated,

705   especially for ellipsoidal bubbles over 3 mm in full-scale aeration processes. For smaller

706   bubbles or millimetric bubbles, mass transfer is more sensitive to water contamination and

707   water quality remains the most important factor.

708   • The impact of water quality on oxygen transfer can be estimated by the contamination angle

709   using comprehensive 1D modeling as developed in this study. This will make it possible to

710   provide a more in-depth understanding of the impact of water quality and the main

711   operating parameters on mass transfer in industrial tanks where the liquid phase is a

712   complex matrix.

Input data

- Physico-chemical parameters
- Column height
- Gas superficial velocity j_G
- Bubble diameter d_B

N layers

$j_G = Q_G/S$
d_B
**Hydrodynamic calculation
(steady state/input for mass transfer)**

- Gas hold-up ε_G
- Slip velocity/gas velocity
- Hydrostatic pressure
- Bubble diameter variation

Mass transfer (dynamic)

- $C_L = f(t)$ (perfectly mixed liquid)
- $C_G = f(t)$ for each height z
