Key words lipophilic contaminant, dioxins and furans, fugacity, risk assessment, meat chemical safety

Introduction

Beef production occasionally faces incidents of contamination with persistent organic pollutants (POPs; e.g. dioxins/furans) that compromise consumers' confidence and induce social distress for farmers (Zennegg, 2018). Understanding and quantifying the POP absorption, distribution, metabolism and excretion (ADME) process in beef cattle is the cornerstone for handling such hazards. This remains highly challenging, as risk assessors have to cope with numerous POPs of distinct physico-chemical properties and with diverse beef farming systems (Driesen et al., 2021, Driesen et al., 2022). The aim was to set-up a generic and integrative mechanistic model for exploring the feed-to-meat accumulation and decontamination kinetics of diverse POPs in beef cattle fed contrasting diets and following different growth rate itineraries.

Material and methods

The physiologically-based toxicokinetic (PBTK) model describes the ADME of POPs depending on their lipophilicity (partition coefficient between octanol and water, K_{ow}) and metabolic clearance in several types (breed, sex, diet) of growing cattle (Figure 1). Consumed pollutants flow to the intestines, where they are excreted in feces, or passively diffuse to the blood (a reverse flux back represent the blood-to-digesta non-biliary excretion). From blood, POPs are distributed between adipose tissues (first to the blood-perfused, later to the deep sub-compartment by passive diffusion; Lerch et al., 2018), muscles, liver and the rest of empty body by advection, according to their blood-perfusion rate. Metabolic clearance is represented in the liver. A model of dynamic transfer in the digestive tract is coupled to a lipid digestion model based on the INRA feeding system (2018). Distribution among tissues depends on body lipid kinetics described by the mechanistic growth model "MECSIC" (Hoch and Agabriel, 2004), including a specific development for the allocation of total body lipid mass to the six body compartments of the ADME model (Figure 1). Hepatic clearance rates were fitted for dioxin/furan congeners based on former toxicokinetic studies. Kinetics of 23478-pentachlorodibenzofuran (23478-PeCDF: moderately lipophilic: K_{ow} 107.1, clearance 0.65 d⁻¹) and octachlorodibenzodioxin (OCDD: highly lipophilic: K_{ow} 108.4, clearance 1.0 d⁻¹) were simulated for Salers heifers that grew slowly (SG; low-energy diet: 9.0 MJ ME/kg DM), fast (FG; high-energy diet: 12.5 MJ ME/kg DM), or with a compensatory growth itinerary (CG; low-energy until 500 kg and high-energy thereafter) from 314 to 700 kg BW. For each treatment, accumulation of POPs in tissues was simulated with a contaminated diet of 0.57 ng TEQ/kg DM (action level for dioxins/furans, EU regulation 277/2012). Decontamination was tested by setting the contamination level to zero after reaching 500 kg BW.

Results and Discussion

The simulated average daily gains were 0.44 in SG, and 1.14 kg/day in FG, but 0.46 until 500 kg BW and 1.34 kg/day thereafter (compensatory growth) in CG heifers. Lipid proportion in empty body increased from 11.7% at 314 kg BW, to 26.8, 28.3, and 27.7% at 700 kg for SG, FG, and CG, respectively. The 23478-PeCDF accumulation kinetics suggested that the regulatory level (2.5 pg TEQ/g lipids, EU regulation 1259/2011) would be overpassed in muscles by 3.8-fold in SG, but would only be 3-fold higher in FG and CG treatments (Figure 2A). Conversely, OCDD concentrations would remain below the regulatory level (Figure 2B). Indeed, when compared to 23478-PeCDF, the higher lipophilicity of OCDD lowered its

absorption rate (Driesen et al., 2022). The decontamination half-life for 23478-PeCDF was lowered by compensatory growth (116 days in CG heifer), when compared to continuous SG (178 days) and FG (126 days). This resulted, at least in part, from a typical dilution effect during decontamination, due to a higher rate of body lipids deposited in CG (0.59 kg/day) than in FG (0.41 kg/day) and SG (0.18 kg/day), in line with previous *in vivo* findings (Driesen et al., 2021).

Conclusion and implications

The use of a mechanistic PBTK model highlighted the complex interplay between POPs' physico-chemical properties and beef cattle lipid kinetics on feed-to-meat accumulation and decontamination rates. Further developments are ongoing to deliver a decision-making tool for risk assessors and managers, and ultimately contribute to beef meat chemical safety.
