10 **Abstract:** Ice slurry is an alternative method to reduce the quantity and emission of greenhouse refrigerants, as  
11 well as control electrical energy consumption. However, the production of ice slurry requires the use of scraped-  
12 surface generators, which are costly to maintain and consume high mechanical energy. Therefore, studying the  
13 icephobic behavior of surfaces is of interest to significantly reduce ice adhesion and facilitate detachment without  
14 the need for mechanical scrapers. This study focuses on the growth, adhesion, and detachment phenomena of ice  
15 by liquid jets on different types of surfaces (hydrophilic, hydrophobic, and superhydrophobic) immersed in a  
16 10 wt.% ethanol/water mixture. A liquid jet is used to detach the ice layer from the surfaces, with a velocity ranging  
17 from 0 to 2.87 m s<sup>-1</sup>, and the surface temperature varies from 25 °C to approximately -9 °C. The results show that  
18 ice adheres less to hydrophilic and hydrophobic surfaces compared to superhydrophobic surfaces. The use of  
19 PTFE-treated aluminum surfaces (hydrophobic) reduces the required flow velocity to detach the ice layer by half  
20 compared to untreated aluminum surfaces (hydrophilic). An ANSYS® Fluent numerical model was developed to  
21 simulate the evolution of turbulent velocities of immersed liquid jets, and a semi-empirical model was designed to  
22 estimate the detachment forces of soft ice from hydrophilic surfaces (untreated aluminum). Two types of ice  
23 detachment from surfaces were identified: adhesive detachment and cohesive detachment.

24 **Keywords:** Ice slurry generator; Superhydrophobic; Icephobic; Ice adhesion; Ice detachment; Liquid jet.

## 25 1. Introduction

26 The upcoming energy and climate crisis is pushing us to seek new ways to optimize energy while  
27 reducing the impact on the environment. This crisis is driven by the increase in global energy  
28 consumption, particularly in the refrigeration sector, where electricity consumption represents about  
29 20% of global consumption. Without considering alternative measures, this proportion will continue to  
30 rise, especially with global warming. Conventional systems of cold production using refrigerant gases  
31 have a significant impact on energy consumption and the environment. Secondary refrigeration offers  
32 an effective solution to significantly reduce the amount of refrigerant gas used, as the cold is transported  
33 by a neutral fluid called secondary fluid to the place of use. When this secondary fluid contains a phase  
34 change material (PCM) [1–3], such as suspended ice particles (ice slurry), electrical energy can be  
35 optimized through thermal storage [4–6]. Ice slurries consist of ice particles suspended in an aqueous  
36 solution with an average diameter of 1 mm or smaller [7]. Transporting cold using ice slurries is a cost-  
37 effective and energy-efficient method because the ice slurry can be stored for extended periods.

38 There are several technologies for cold storage using ice, including ice harvesting, external ice-on-  
39 coil fusion systems, internal ice-on-coil fusion systems, encapsulated ice systems, and ice slurry [8].  
40 These systems, based on Cold Thermal Energy Storage (CTES) using the latent heat of fusion of water  
41 (335 kJ kg<sup>-1</sup>), allow storing thermal energy in the form of ice during periods of low cooling demand, to  
42 be later released when demand is higher [8–11].

43 Afsharpanah et al. [9] conducted a numerical study to examine the charging performance of a thermal  
44 energy storage device based on ice. This device consists of a small cuboid container equipped with two  
45 rows of serpentine tubes with connecting plates. Designed as a backup cooling system for domestic

46 refrigerators in developing countries, this device aims to compensate for thermal load during frequent  
47 power outages in those regions and to preserve food during such times.

48 The authors' [9] study highlights key parameters that influence the charging performance of the ice  
49 storage device. The results show that certain dimensions and characteristics of the system can be  
50 optimized to improve the charging rate, which could be beneficial for cooling backup applications in  
51 developing countries, especially during frequent power outages. These interesting findings pave the way  
52 for potential future improvements in the design and use of such domestic energy storage, contributing  
53 to better food preservation and increased energy efficiency in refrigeration systems.

54 Ice slurry is used in many fields such as medical care, the food industry, firefighting, air conditioning  
55 [2], and other industrial applications [12].

56 There are several ice slurry generators, which can be classified into two categories [13,14]:

- 57 ➤ Generators with moving components that are directly related to the extraction of ice from  
58 the surface (scraped or brushed surface generator) [15] or the transformation of ice blocks  
59 into ice slurry by grinding (falling film generator), etc. [13,14].
- 60 ➤ Generators without moving parts such as the supercooling generator, direct contact ice slurry  
61 generator [16,17], and vacuum ice slurry generator [18], etc. [14].

62 Most ice slurry generators without moving parts, excluding the ice slurry generator using the  
63 supercooling phenomenon, are at the prototype or laboratory study technology readiness level (TRL),  
64 with a TRL between 1 and 5 [14]. The most industrially advanced generators with a moving component  
65 are scraped or brushed surface generators, while the most advanced generators without a moving  
66 component are ice slurry generators that utilize the supercooling phenomenon.

67 However, these two types of generators have disadvantages:

- 68 ➤ The ice slurry generator using the supercooling phenomenon can be blocked because of the  
69 uncontrolled breakdown of the supercooling inside the generator, as well as the formation and  
70 agglomeration of the ice inside the device, thus resulting in discontinuous production of ice  
71 slurry.
- 72 ➤ Generators with scraped or brushed surfaces have disadvantages such as low energy efficiency  
73 (additional mechanical energy consumption for the rotation of the scrapers) and high  
74 maintenance costs due to the wear of the scrapers [14].

75 To address these drawbacks, researchers working in the refrigeration industry have developed new  
76 experimental approaches to optimize ice slurry production without using moving components. These  
77 approaches include: the production of ice slurry by hydro scraping with intermittent flow and reduced  
78 cooling energy at the time of ice detachment [19], the use of smooth and/or low surface energy materials  
79 such as nylon 11 or polytetrafluoroethylene (Teflon® or PTFE) to reduce ice adhesion and facilitate ice  
80 detachment by flow [20,21], the use of additives to make the ice morphology softer (porous ice or ice  
81 with needle-shaped crystals), resulting in its reduced contact surface with the exchanger walls and thus  
82 decreasing its adhesion to the surface [22], and the use of icephobic or superhydrophobic coatings to  
83 increase the supercooling degree in supercooling generators [23–30].

84 However, none of these methods are ready for industrial use, and there is a lack of visual analysis to  
85 better understand the phenomenon of ice detachment from surfaces. For example, studies of ice slurry  
86 production by hydro scraping in a PTFE or nylon 11 helical tube heat exchanger (HCHX) [20,21], as  
87 well as in steel tube heat exchangers [19], have been performed with compact tube heat exchangers that  
88 are not transparent. This lack of visibility makes it difficult to establish an empirical or semi-empirical  
89 relationship between flow velocity and ice detachment. In addition, these tubular heat exchangers often  
90 experience clogging problems due to ice agglomeration in the tubes, making it difficult to study ice  
91 detachment. Although Zhao et al. [22] focus on visualization, their study does not provide a complete

92 visualization of ice detachment by flow because it is only based on the decrease in ice thickness, rather  
93 than the lengthwise detachment of the ice from the surface. These studies deserve further investigation  
94 with the visualization of ice detachment phenomena on the surface by flow (also called hydro-scraping  
95 or by the hydrodynamic effect). The variation of flow velocity, surface temperature, and surface states  
96 (hydrophilic, hydrophobic, superhydrophobic) are also parameters to consider in order to better  
97 understand ice adhesion and detachment phenomena.

98 The present work is the first study on the ice detachment by a liquid jet with variable velocities on  
99 immersed surfaces. The main objective of this study is to understand the phenomena of growth,  
100 adhesion, and detachment of ice by flow on different types of surfaces (different wettability and surface  
101 conditions). It aims at optimizing the ice slurry production method to develop a new method for ice  
102 slurry production without moving components. To achieve these objectives, three types of surfaces  
103 (hydrophilic, hydrophobic, and superhydrophobic) were studied in a transparent rectangular device  
104 placed on a loop circulating a 10 wt.% ethanol/water mixture. This device is also equipped with a heat  
105 exchanger for crystallization and a rectangular nozzle for liquid jet generation. This study focuses on  
106 understanding the effect of temperature and surface condition on the growth and detachment of ice on a  
107 given surface. Additionally, it examines the effect of increasing liquid jet velocity on ice detachment to  
108 select surfaces with less adhesion and seek the most optimal conditions. The originality of this study lies  
109 in the visualization of ice growth and detachment phenomena by a liquid jet (flow) on submerged  
110 surfaces and in the evaluation of the ice detachment length ( $L_D$ ) along a surface as a function of the flow  
111 velocity. This is done to establish an empirical relationship and to understand the ice detachment  
112 phenomena in immersion. Thus, an ANSYS® Fluent numerical model was developed to simulate the  
113 evolution of turbulent velocities of immersed liquid jets along the heat exchanger surface for comparison  
114 with experimental results.

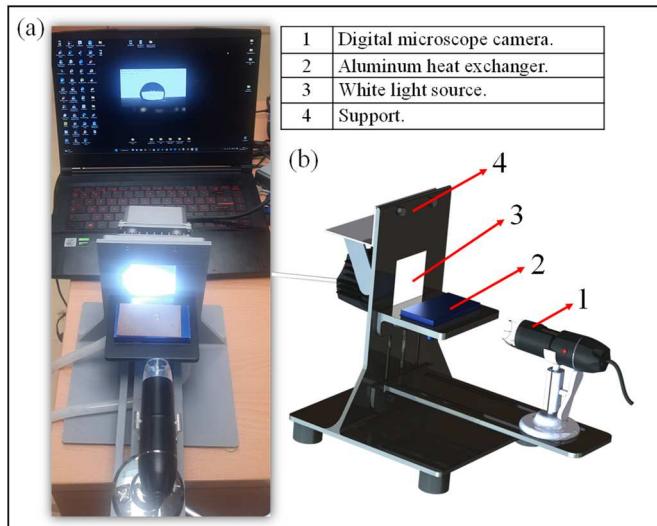

## 115 **2. Materials and methods**

116 The objective of this study is to better understand the phenomena of ice adhesion and detachment in  
117 immersion on several types of surfaces with different wettability and surface states to develop a new ice  
118 slurry generator without moving components. Therefore, two devices were developed. Firstly, a device  
119 to measure contact angles (CA) on the studied surfaces, and secondly, a device to identify the surfaces  
120 that allow optimal ice detachment by shear flow (liquid jet) of a 10 wt.% ethanol/water mixture through  
121 a rectangular nozzle. This section is composed of four subsections: the first describes the experimental  
122 setups for measuring contact angles; the second describes the experimental setups for the study of ice  
123 growth and detachment by flow; the third describes the experimental protocol for the ice detachment  
124 setup; and the fourth sub-section describes the numerical model developed using ANSYS Fluent 2021  
125 R1 to simulate the evolution of turbulent liquid jet velocities in immersion. The aim of this simulation  
126 is to make a comparison with experimental results and to understand why, at a certain speed, the ice no  
127 longer detaches itself from the surface studied. The overall objective is to establish an empirical  
128 relationship between jet velocity variation and ice detachment lengths ( $L_D$ ).

### 129 **2.1 Experimental set-up for wettability and roughness analysis**

130 An original goniometer was developed for wettability analysis (contact angle measurement) on  
131 different surfaces and was presented in detail in a previous work [28]. The device is shown in Figure 1.  
132 This goniometer is equipped with a USB CMOS digital microscope camera from Chengstore with  
133 640 x 480 resolution and x1600 zoom, a white light source, an aluminum heat exchanger to maintain  
134 the temperature of the samples at a fixed value, and a circulating cryostat bath to control the surface  
135 temperature of the heat exchanger. The camera is connected to a computer to measure the contact angle  
136 (CA) using the IC Measure V2.0.0.286 software. Roughness analysis of the three surface types  
137 (hydrophilic, hydrophobic, and superhydrophobic) was performed using a KEYENCE VHX-

138 7000N/VHX-970N digital microscope. The results of the contact angle and roughness measurements  
139 are presented in the results section.

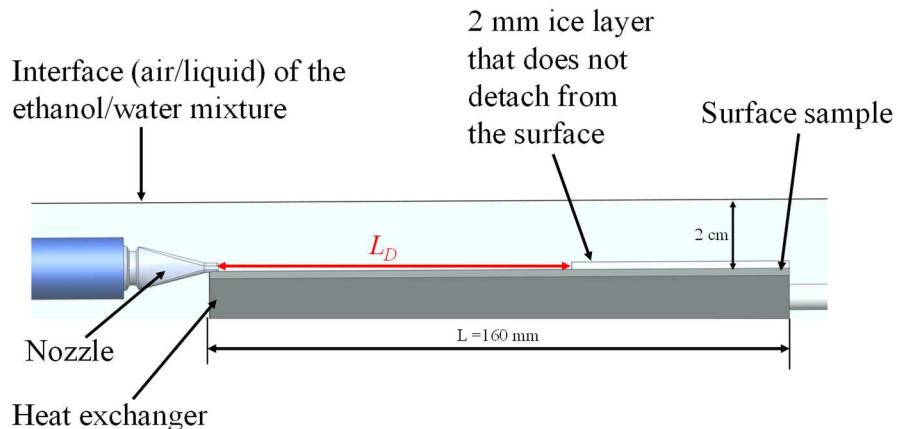

140  
141 **Figure 1** – Contact angle measuring device, (a) real image of the goniometer; (b) design image of the goniometer on  
142 SOLIDWORKS.

143 Three AW1050H24 aluminum surface samples are used to represent different wetting and surface  
144 states: hydrophilic, hydrophobic, and superhydrophobic, to characterize their ability to reduce ice  
145 adhesion. The first surface is an untreated aluminum surface. The second surface of the same material  
146 (aluminum) is treated with a 13  $\mu\text{m}$  thick PTFE adhesive tape from REKALARO. This tape is made of  
147 a PTFE-coated fiberglass fabric, which gives it additional properties of tear, tensile, and puncture  
148 resistance. The third surface is treated with a commercial superhydrophobic "Ultra Ever Dry" (UED)  
149 coating applied in two layers by spraying, the preparation process of which is described in detail in an  
150 earlier study [28].

## 151 **2.2 Experimental device of ice detachment study**

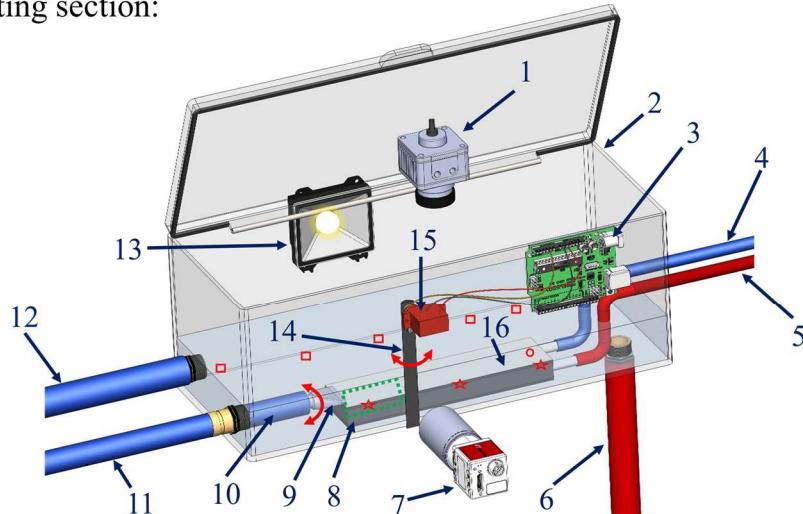

152 To investigate the detachment of the ice layer on the three surfaces described in subsection 2.1, a  
153 system was developed for and presented in Figure 2. This system consists of a BEWINNER aluminum  
154 heat exchanger (component 8 in Figure 3) with dimensions 0.16 m x 0.04 m x 0.012 m (length, width,  
155 height), which is insulated on all sides, except for the top side where the surface samples are fixed with  
156 thermal paste. To remove the ice on the surface, a liquid jet is projected onto the surface through an  
157 ARIANA flat nozzle (component 9 in Figure 3) with a rectangular ( $S_N$ ) outlet section measuring  
158 30 mm x 2 mm. The entire system is immersed in a 10 wt.% ethanol/water mixture with an immersion  
159 depth of 2 cm between the surface sample and the air/liquid interface. The ice detachment length ( $L_D$ ) is  
160 defined as the maximum distance between the nozzle outlet section and the remaining ice layer on the  
161 surface at the furthest point.

162  
163 **Figure 2** – Schematic representation of the ice detachment length  $L_D$  by a liquid jet flow along the surface sample.

164 The experimental setup shown in Figure 2 is placed in a transparent box made of  
 165 Polymethylmethacrylate (PMMA), which is identified as component 2 in Figure 3. The dimensions of  
 166 the box are 0.34 m x 0.146 m x 0.127 m (length, width, height). This entire setup is called the surface  
 167 testing section, and it includes a high-speed camera (component 7 in Figure 3), specifically the  
 168 monochrome camera AOS Cesyco PROMON U750, which has a recording speed of 750 frames per  
 169 second and a KOWA zoom lens with a fixed resolution of 640 x 480. The section viewed by this camera  
 170 is shown in Figure 3 as a green dashed square, clearly representing the observed region. The video  
 171 recording of the ice layer formation and its detachment by the flow is performed using the AOS Imaging  
 172 Studio software version 4.7.2.4. Additionally, a second digital camera is placed above the exchanger to  
 173 take pictures after the ice detachment (component 1 in Figure 3). The ice detachment length,  $L_D$ , is  
 174 measured using IC Measure software version 2.0.0.286. To remove the dew that forms on the surface of  
 175 the PMMA box during the cooling of the mixture and for better visualization of the formation and  
 176 detachment of the ice layer by the liquid jet, a servo motor (component 15 in Figure 3) equipped with a  
 177 wiper (component 14 in Figure 3) is installed. The servo motor is controlled by an ELEGOO UNO R3  
 178 controller board (component 3 in Figure 3), which is programmed to allow the wiper to make a round  
 179 trip every 4 seconds with an opening angle of 120°. The nozzle is fed by the pump integrated into the  
 180 circulating cryostat (component III in Figure 4) through a filling tube (components 11 and 10 in  
 181 Figure 3), with an adjustable mass flow rate from 0 to 0.167 kg s<sup>-1</sup>. Finally, the PMMA box is  
 182 continuously fed through a filling tube (component 12 in Figure 3) that connects to an external pump  
 183 component (component IV in Figure 4) that takes liquid from the circulating cryostat (component III in  
 184 Figure 4) with a constant mass flow rate of 0.151 kg s<sup>-1</sup> during experiments.

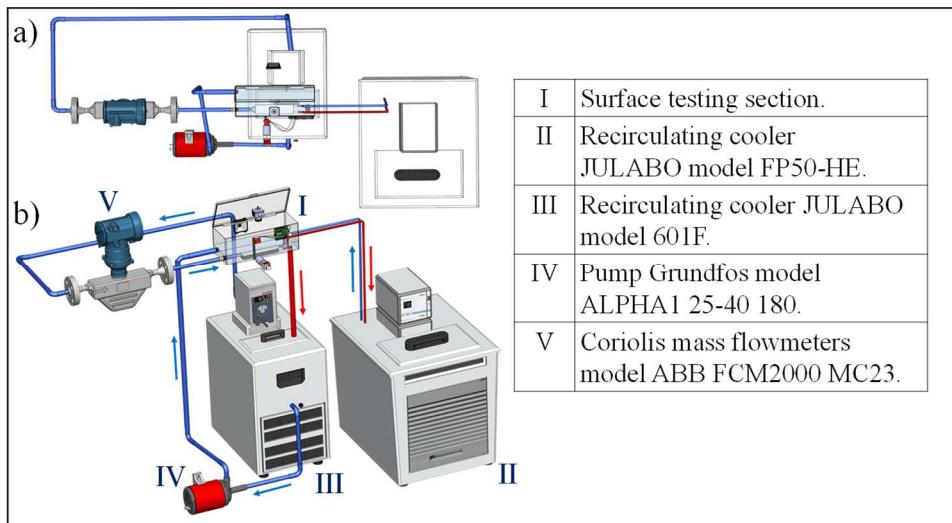

Surface testing section:

1	Digital camera.
2	Polymethylmethacrylate (PMMA) box 0.34 m x 0.146 m x 0.127 m (length, width, height).
3	ELEGOO UNO R3 controller board.
4	50 wt.% ethanol-water mixture inlet.
5	50 wt.% ethanol-water mixture outlet.
6	Liquid mixture outlet.
7	AOS Cesyco PROMON U750 high speed monochrome camera and KOWA zoom lens . Image resolution 640 x 480
8	Bewinner aluminum heat exchanger 0.16 m x 0.04 m x 0.012 m (length, width, height).
9	ARIANA flat nozzle with 0.03 m x 0.002 m (width, height) outlet section.
10	Nozzle swivel tube.
11	Nozzle supply tube.

13	A-LED LIGHTING 15 Watt.
14	Wiper.
15	Servo motor SG90.
16	Surface sample.

Figure 3 – Detailed schematic of the surface testing section, highlighting its components that make it up (component I of Figure 4)

The measurement of temperatures on the surface testing section is carried out using several T-type thermocouples with a measurement uncertainty of  $\pm 0.03$  °C. These thermocouples are connected to a KEYSIGHT Model DAQ970A data acquisition system connected to a computer. A thermocouple is placed on the surface sample approximately 150 mm from the nozzle outlet section, shown in Figure 3 by a red circle. The purpose of placing a single thermocouple on the sample surface is to minimize disturbance during ice formation and detachment. Tests were performed to verify the homogeneity of the temperature along the sample surface and the average difference over several points that does not exceed  $\pm 0.5$  °C. This result validates the use of a single thermocouple on the surface. Three thermocouples are placed between the surface sample (component 16 in Figure 3) and the heat exchanger (component 8 in Figure 3) and are represented in Figure 3 by red stars. Five thermocouples are placed in the surface testing section to measure the temperature of the aqueous mixture at different locations, represented in Figure 3 by red squares.

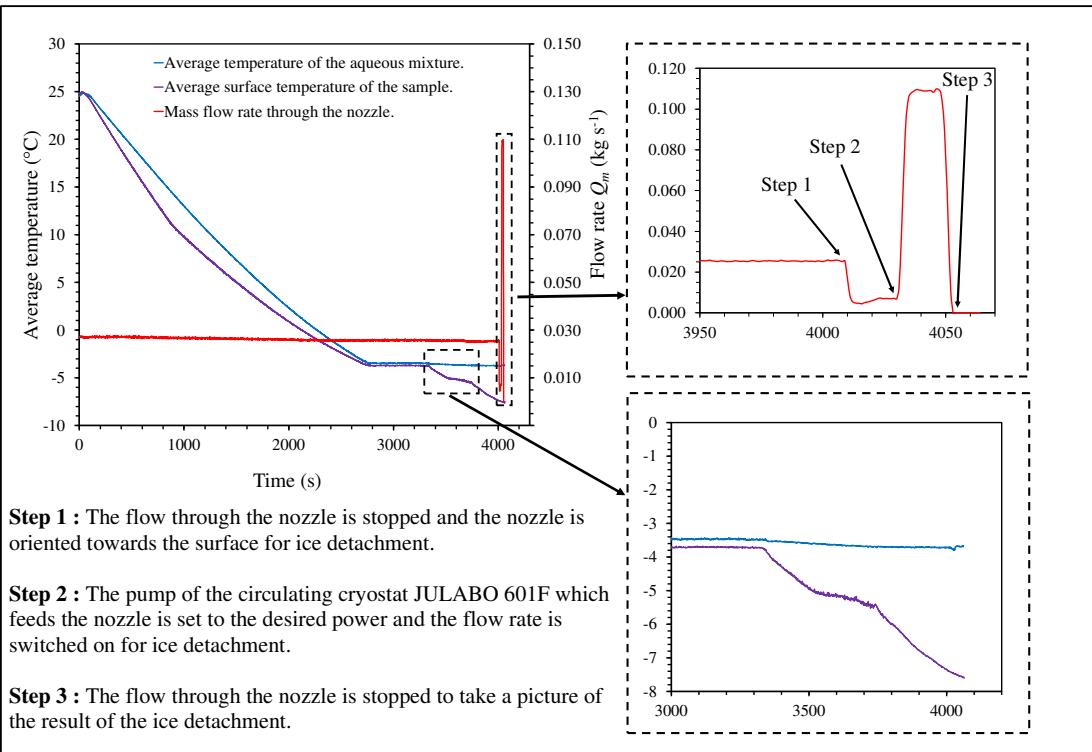

200  
201  
202 **Figure 4** – Schematic of the experimental setup to study ice detachment by flow on different surfaces: (a) top view;  
(b) perspective view.

203 Figure 4 shows the complete experimental setup of ice detachment by shear flow. This device is  
204 composed of a surface testing section (component I in Figure 4), two circulating cryostats JULABO  
205 model FP50-HE (component II in Figure 4) and 601F (component III in Figure 4), a Grundfos pump  
206 model ALPHA1 25-40 180 (component IV in Figure 4), and an ABB Coriolis mass flow rate meter  
207 model FCM2000 MC23 (component V in Figure 4). The entire setup is placed in a climate chamber at  
208 a fixed temperature of 13 °C to improve the efficiency of the two circulating cryostats and for reducing  
209 heat losses of the experimental setup.

210 **2.3 Experimental parameters and protocols**

211 The experimental protocol for the study of ice growth and detachment by flow (liquid jet) is as  
212 follows: first, the pump (component IV in Figure 4) feeding the surface testing section (system shown  
213 in Figure 3) is turned on and set at a mass flow rate of  $0.151 \text{ kg s}^{-1}$ , establishing a water level of 2 cm  
214 above the heat exchanger. Then, a circulation of the aqueous mixture is established at a constant mass  
215 flow rate of  $0.025 \text{ kg s}^{-1}$  through the tube feeding the nozzle. As shown in Figure 5, which represents  
216 the evolution of the mass flow rate through the nozzle, as well as the temperature of the aqueous mixture  
217 (10 wt.% ethanol/water) and the untreated aluminum surface during cooling.

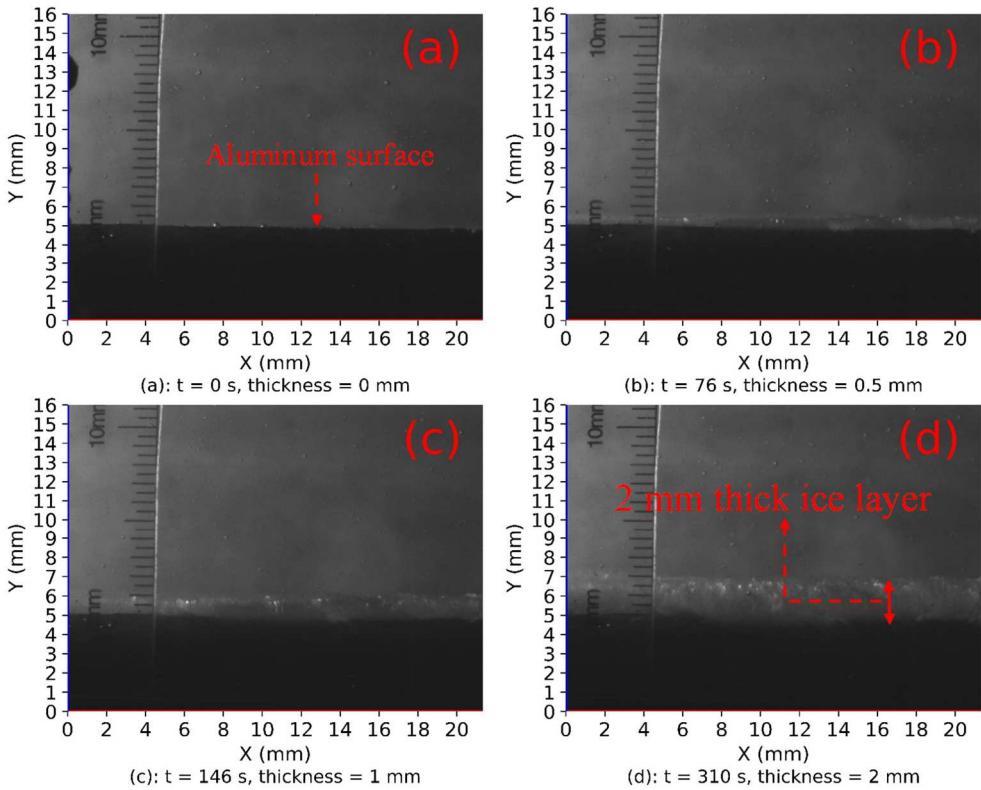

218  
219  
220  
221

**Figure 5**– Example of evolution of the mass flow rate through the nozzle and the average temperature of the aqueous mixture (10 wt.% ethanol/water mixture) and the average temperature of the untreated aluminum surface (hydrophilic) during the cooling process.

222 The purpose of maintaining the flow in the tube feeding the nozzle (components 11 and 10 in  
223 Figure 3) is to avoid heating of the liquid mixture at the time of the jet projection for the detachment of  
224 the ice layer. Indeed, if the flow is stopped, since the ambient temperature is fixed at 13 °C, heating of  
225 the liquid can occur in the tube feeding the nozzle. The nozzle (component 9 in Figure 3) is oriented at  
226 about 80° upwards to avoid disturbing the formation of the ice layer. Then, the temperature of the two  
227 circulating cryostats (components III and II in Figure 4) that supply the heat exchanger and the surface  
228 testing section, respectively, is set to an initial temperature of 25 °C. Then, the temperature of the two  
229 circulating cryostats is lowered to achieve stable surface sample and aqueous mixture temperatures at a  
230 value of -3.6 °C before crystallization, as shown in Figure 5. Once the surface and liquid mixture  
231 temperature are stabilized at -3.6 °C, the sample surface temperature is then lowered to a desired value  
232 to initiate crystallization. In the case of Figure 5, the desired surface temperature was -8 °C.  
233 Crystallization occurs at the phase change temperature of -4.8 °C to form a 2 mm ice layer on the surface  
234 sample immersed in the 10 wt.% ethanol/water mixture, as shown in Figure 6. In Figure 6, the ice layer  
235 formation takes about 310 seconds on the untreated aluminum surface. The thickness of the ice layer is  
236 set to 2 mm so as not to penalize the heat transfer and to avoid the problem of temperature control.

237  
238  
239  
240  
241  
242

243  
244  
245 **Figure 6** – Evolution of the ice layer thickness that forms on an untreated aluminum surface in a  
10 wt.% ethanol/water mixture at a surface temperature set at  $-8^{\circ}\text{C}$ , (a): before crystallization; (d): after crystallization.

246 During these experiments, temperature and mass flow rate recording through the nozzle are activated  
247 using KEYSIGHT software. The high-speed camera (component 7 in Figure 3) is activated to record  
248 video of the ice layer formation and its detachment by the flow, and the wiper (component 14 in  
249 Figure 3) is turned on to avoid condensation problems. After the ice layer is formed, the flow of the  
250 aqueous mixture through the nozzle is stopped, and then the nozzle is directed horizontally towards the  
251 surface sample under investigation (downwards) so that the shear flow loosens the ice layer (step 1 in  
252 Figure 5). Next, the mass flow rate through the nozzle is adjusted to the desired value (in Figure 5, the  
253 set flow rate is  $0.109 \text{ kg s}^{-1}$ , which corresponds to a flow velocity of  $1.83 \text{ m s}^{-1}$  at the nozzle outlet), and  
254 the flow rate is turned on so that the liquid jet exiting the nozzle loosens the ice layer, as shown in Step  
255 2 of Figure 5. Finally, the filling pump (component IV in Figure 4) and the cryostat circulation pump  
256 (component III in Figure 4) are turned off (step 3 in Figure 5) when the ice layer no longer detaches  
257 from the surface. A picture of the surface is taken with a camera (component 1 in Figure 3), and the ice  
258 detachment length ( $L_d$ ) is measured using IC Measure image processing software version 2.0.0.286.

## 259 **2.4 Numerical model for the turbulent jet velocity evolution simulation in immersion**

260 A numerical model is developed to simulate the evolution of the velocity of a turbulent jet in  
261 immersion using the ANSYS® FLUENT 2021 R1 software. Several authors have already investigated  
262 hydrodynamic phenomena of turbulent liquid jets in immersion, both experimentally and numerically.  
263 However, these works do not specifically address the detachment of ice in immersion [31–33]. The  
264 objective of our numerical study is to track the evolution of the velocities of the turbulent liquid jet in  
265 immersion along the surface of the untreated aluminum sample and does not take account for ice  
266 formation and detachment. In our experiment, after the ice detachment, the liquid jet is not immediately  
267 stopped; instead, it is allowed to continue for a period of time to ensure that the ice layer no longer  
268 detaches and to observe a phenomenon in a steady-state regime. Our simulation hypothesis focuses  
269 solely on the evolution of liquid jet velocities over a plane plate within a water-ethanol binary mixture

270 without ice layer, due to the lack of data on ice adhesion forces. The purpose of these simulations is to  
 271 uncover the reasons behind the detachment of the ice layer at a specific length for each studied velocity,  
 272 aiming to comprehend the detachment phenomenon. The ultimate goal is to establish a relationship  
 273 between the experimentally determined ice detachment length ( $L_D$ ) and the numerically determined  
 274 maximum turbulent jet length ( $L_{max}$ ), at which the liquid jet velocity reaches the minimum velocity at  
 275 which ice detachment does not occur.

276 The Reynolds number of turbulent liquid jets in these simulations is calculated with equation (Eq.1):

$$277 \quad R_e = \frac{\rho_l V_N D_H}{\mu} \quad \text{Eq. (1)}$$

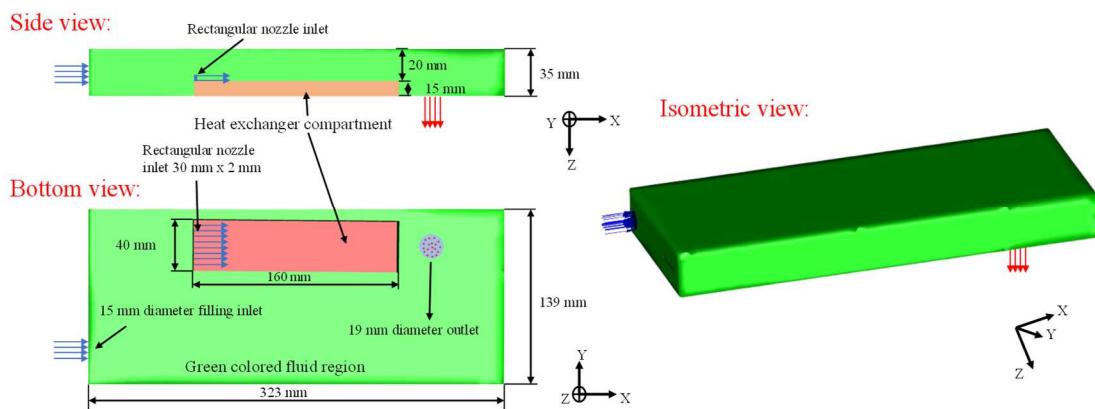

277 Where  $D_H$  is the hydraulic diameter of the nozzle, which is 0.00375 m,  $\rho_l = 983.4 \text{ kg m}^{-3}$  is the  
 278 density of the 10 wt.% ethanol/water mixture at the liquid temperature, which is set at  $-3.6^\circ\text{C}$ ,  $V_N$  is the  
 279 turbulent velocities at the nozzle outlet (ranging from 1.4 to 2.87 m s $^{-1}$ ), and  $\mu = 0.001889 \text{ Pa s}$  is the  
 280 dynamic viscosity of the 10 wt.% ethanol/water mixture at the liquid temperature, which is set at  
 281  $-3.6^\circ\text{C}$ . The results of the Reynolds number  $R_e$  are shown in Table 1. The value of the Reynolds number  
 282  $R_e$  is greater than 2300, so the velocity of the liquid jet, ranging from 1.4 to 2.87 m s $^{-1}$ , is in the turbulent  
 283 regime.

284 **Table 1** – Reynolds number of turbulent velocities at the nozzle outlet.

Velocity in nozzle outlet (m s $^{-1}$ )	Reynolds $R_e$ ( $\text{f}$ )
2.87	5545
2.45	4783
2.04	3983
1.87	3651
1.62	3163
1.40	2733

#### 285 **2.4.1 Geometry, boundary conditions and meshing**

286 The fluid domain geometry of the surface testing section (Figure 3) has been modeled using  
 287 ANSYS® SpaceClaim 3D CAD Modeling Software, as illustrated in Figure 7. The dimensions of the  
 288 geometry and the specifics of the boundary conditions have also been provided in the same Figure.  
 289 Table 2 summarizes the boundary conditions that have been defined in the Fluent software. The mesh  
 290 was created using Fluent mesh software. It is a hybrid mesh consisting of tetrahedral and hexacore  
 291 meshes, as shown in Figure 8.

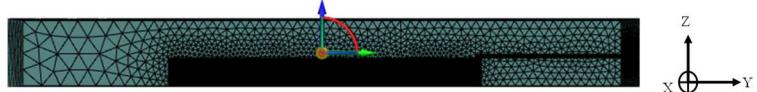

292 **Figure 7** – 3D geometry of the fluid domain of the surface testing section drawn on ANSYS® SpaceClaim 3D CAD

#### 2.4.2 Numerical discretizations

301 The ANSYS® Fluent 2021 R1 software was used to perform a 3D steady-state simulation of a  
 302 turbulent liquid jet in immersion. The turbulence model chosen was the k-epsilon Realizable with  
 303 Enhanced Wall Treatment. The Coupled algorithm was used to couple the velocity and pressure. The  
 304 spatial Second Order discretization scheme was used to discretize the pressure, while First Order  
 305 Upwind was used for the momentum, turbulent kinetic energy, and turbulent dissipation energy.  
 306 ANSYS® Fluent's default relaxation values were used for the parameters of pressure, density, body  
 307 force, and turbulent viscosity, with 0.3 for the momentum and 0.7 for turbulent kinetic energy and  
 308 turbulent dissipation energy. The computational results were considered convergent when the residual  
 309 was less than  $10^{-6}$  for all equations and stabilized. The analyzed results are presented in subsection 3.3.1.

#### 2.4.3 Grids Sensitivity and Model Validation

311 The grid independence has been carefully examined to ensure the reliability of the numerical  
 312 simulation results. For this purpose, five different grids were analyzed to observe the solution's  
 313 evolution, result stability, and grid sensitivity. The grid sets used consisted of 905,060 cells (grid 1);  
 314 1,628,877 cells (grid 2); 2,753,589 cells (grid 3); 4,485,553 cells (grid 4); and 6,001,644 cells (grid 5).  
 315

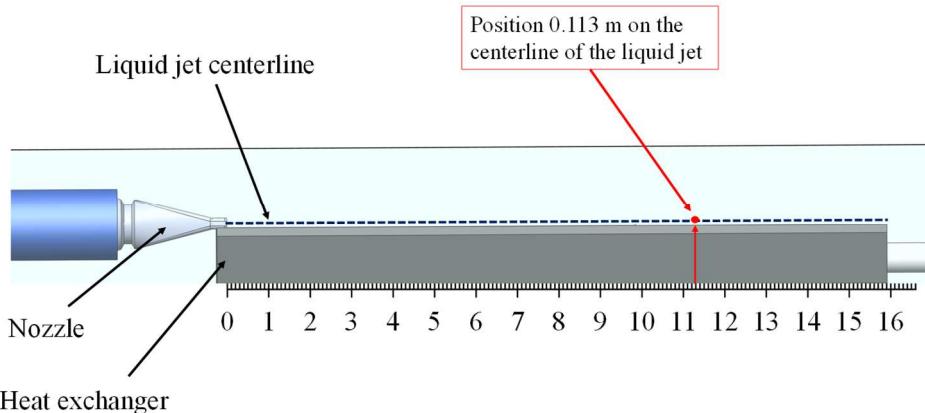

316 In the mesh test simulation, the liquid jet velocity at the nozzle outlet is set at  $1.4 \text{ m s}^{-1}$ . During its  
 317 evolution, this velocity decreases until reaching lower speeds for the detachment of the ice, which has  
 318 already been experimentally determined (see section 3.3). For instance, in the experimental case where  
 319 the liquid jet velocity is set at  $1.4 \text{ m s}^{-1}$ , the ice detachment length is  $0.116 \text{ m}$  at a temperature of  $-6 \text{ }^{\circ}\text{C}$   
 320 (see Table 3), and the experimentally found ice non-detachment velocity is  $0.51 \text{ m s}^{-1}$  (see Figure 22).  
 321

322 The parameter evaluated during the mesh sensitivity test simulations is the jet velocity along the  
 323 central line at position  $0.113 \text{ m}$  (see Figure 9, with the nozzle outlet considered as the origin), where the

324 jet velocity reaches values at which detaching the ice layer is no longer possible experimentally at a  
 325 speed of  $0.51 \text{ m s}^{-1}$  (see Figure 23 and Table 3). The results of the effect of increasing the number of  
 326 mesh elements on the solution evolution are presented in Figure 10. It is worth noting that, according to  
 327 this figure, the results are independent of the grid size for a number of elements greater than 2,753,589  
 328 cells.

329

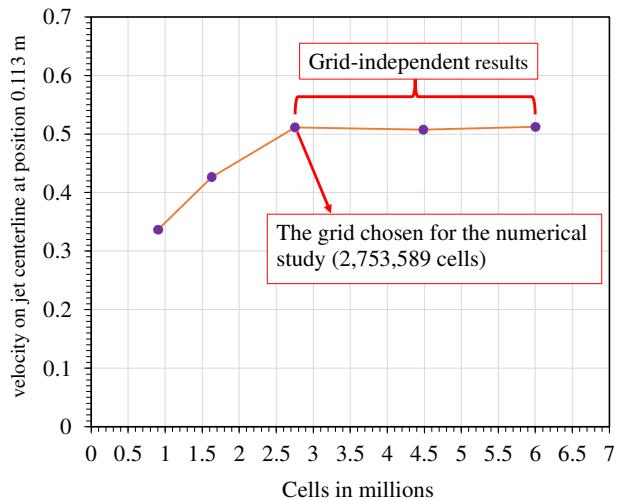

330 Considering the simulation's accuracy and computational efficiency, the final number of cells for this  
 331 study was set to 2,753,589 to reduce the computation time, as using 6,001,644 cells would result in a  
 332 24-hour calculation time.

333

334 **Figure 9** – Spatial representation of the position 0.113 m on the central line of the liquid jet, where the velocity is calculated  
 335 to test grid independence.

336

337

338 **Figure 10** – Evolution of liquid jet velocity result on its central line at the position 0.113 m as a function of the number of  
 339 grid cells studied.

340

### 3. Results and discussions

341 In this section, the results were analyzed and discussed regarding the effect of temperature, surface  
 342 conditions (roughness and wetting properties) on the growth, adhesion, and detachment of the ice layer  
 343 by the flow. The objective is to better understand these phenomena in immersion to determine the  
 344 optimal conditions for ice slurry production.

345

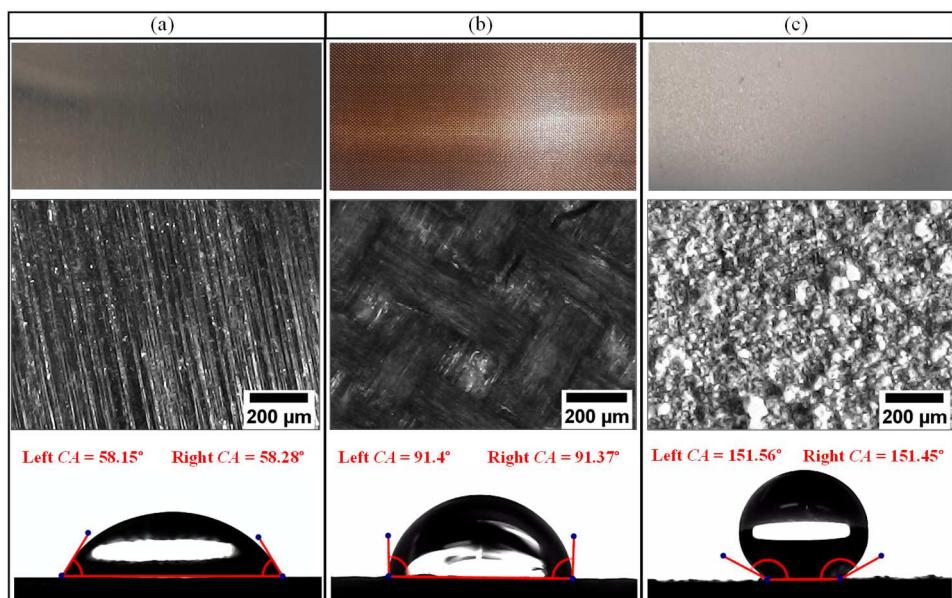

#### 3.1 Wettability and surface roughness characterization

346

Surface wettability is divided into three categories [34,35]:

347 ➤ hydrophilic surfaces are characterized by a contact angle (*CA*) with a drop of water of less than  
 348 90°.  
 349 ➤ hydrophobic surfaces are characterized by a contact angle of greater than 90° and less than 150°.  
 350 ➤ Superhydrophobic surfaces are characterized by a contact angle of greater than 150° and a  
 351 contact angle hysteresis *CAH* < 10°.

352 Three types of AW1050H24 aluminum surfaces (hydrophilic (reference), hydrophobic, and  
 353 superhydrophobic) were characterized to determine their ability to reduce ice adhesion. The liquid drop  
 354 volume used for characterization is 8.4  $\mu\text{L}$  of a 10 wt.% ethanol/water mixture, this volume being neither  
 355 too large to avoid crushing of the drop by gravity effect nor too small to avoid surface tension effects.  
 356 Measurements are repeated 4 times at an ambient temperature of 23 °C to verify the non-variation of the  
 357 contact angle, the uncertainty is about  $\pm 1^\circ$ . The first surface is made of untreated (hydrophilic) aluminum  
 358 and exhibits an average contact angle (average of left and right contact angles) of 58.21°, as shown in  
 359 Figure 11 (a), while this surface forms an average contact angle of 82.36° with a drop of deionized water  
 360 [28,29]. The second aluminum surface (same material) which is treated with the 13  $\mu\text{m}$  thick PTFE  
 361 adhesive tape presents an average contact angle of 91.38°, as shown in Figure 11 (b). The third surface,  
 362 which is treated with the commercial superhydrophobic coating "Ultra Ever Dry" (UED), exhibits an  
 363 average contact angle of 151.50°, as shown in Figure 11 (c). This coating was already characterized in  
 364 a previous study with a deionized water drop of 8.4  $\mu\text{L}$ , with an average contact angle of 157.59° in the  
 365 Cassie state [28,29].

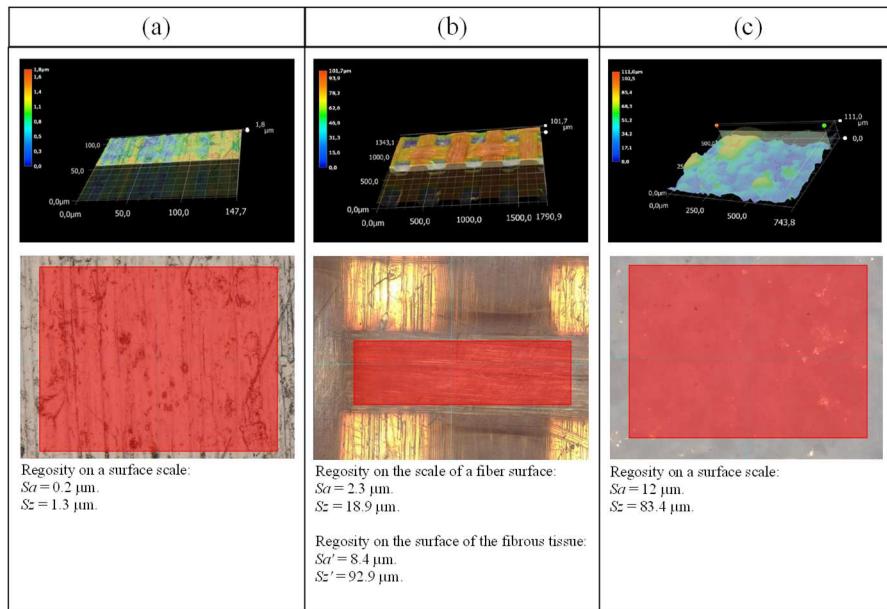

366  
 367 **Figure 11** – Microscopic images and contact angles of the three types of surfaces studied, (a) hydrophilic "untreated  
 368 aluminum"; (b) hydrophobic "aluminum treated with PTFE adhesive tape"; (c) superhydrophobic "aluminum treated with  
 369 UED coating".

370 The roughness analysis of the three types of surfaces studied was performed using a KEYENCE  
 371 VHX-7000N/VHX-970N digital microscope. Figure 12 presents the results of the measurement of the  
 372 surface roughness parameter *S<sub>a</sub>*, which is the arithmetic mean height. This parameter *S<sub>a</sub>* extends the *R<sub>a</sub>*  
 373 parameter (arithmetic mean height of a line) to a surface, while the surface roughness *S<sub>z</sub>* represents the  
 374 maximum height. This *S<sub>z</sub>* parameter is defined as the sum of the maximum peak height value and the  
 375 greatest well depth in the defined area. As seen in Figure 12 (a), the untreated aluminum (hydrophilic)  
 376 surface has the lowest surface roughness (*S<sub>a</sub>* = 0.2  $\mu\text{m}$  and *S<sub>z</sub>* = 1.3  $\mu\text{m}$ ). The aluminum surface treated  
 377 with PTFE adhesive ribbon (hydrophobic) has a double surface roughness, one at the scale of a single  
 378 fiber (*S<sub>a</sub>* = 2.3  $\mu\text{m}$  and *S<sub>z</sub>* = 18.9  $\mu\text{m}$ ) and the other at the scale of fibrous tissue surface (*S<sub>a'</sub>* = 8.4  $\mu\text{m}$   
 379 and *S<sub>z'</sub>* = 92.2  $\mu\text{m}$ ), as shown in Figure 12 (b). The aluminum surface treated with UED coating  
 380 (superhydrophobic), as shown in Figure 12 (c), has the highest surface roughness (*S<sub>a</sub>* = 12  $\mu\text{m}$  and

381  $S_z = 83.4 \mu\text{m}$ ) compared to the surface roughness of the untreated aluminum and the surface roughness  
 382 of a single fiber of the PTFE tape.

383

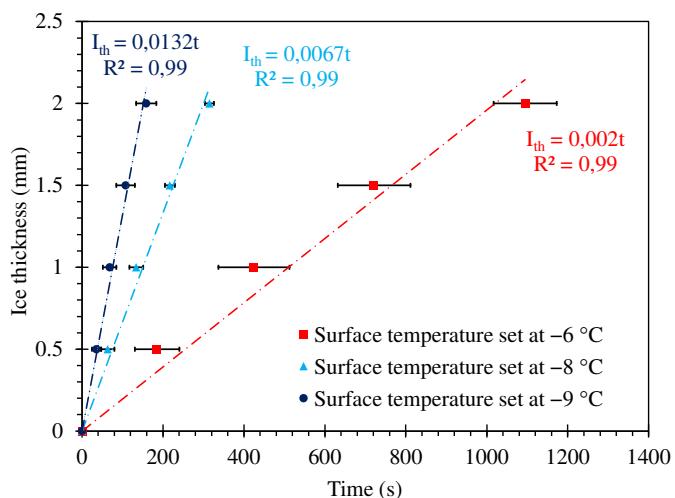

384  
 385 **Figure 12** – Results of the measurement of surface roughness parameters "Sa" and "Sz" of the three types of surfaces studied:  
 386 (a) hydrophilic; (b) hydrophobic and (c) superhydrophobic.

387 **3.2 Ice growth kinetics**

388 The effect of decreasing surface temperature on ice type and ice growth kinetics on the untreated  
 389 aluminum surface was examined. In addition, the effects of surface roughness on ice growth kinetics  
 390 were also analyzed on three types of surfaces: hydrophilic (untreated aluminum), hydrophobic  
 391 (aluminum treated with PTFE adhesive tape), and superhydrophobic (aluminum treated with UED  
 392 coating).

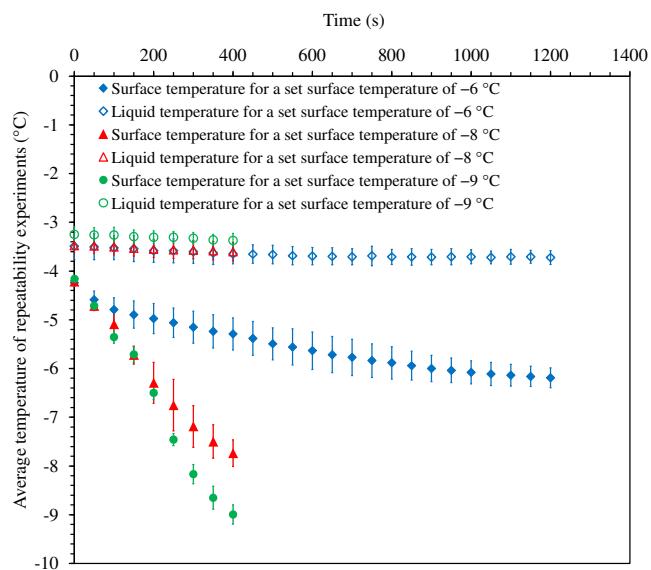

393 **3.2.1 Temperature effect on ice growth kinetics**

394 Figure 13 shows the growth kinetics of an ice layer up to 2 mm thick on an untreated aluminum  
 395 surface (hydrophilic) as a function of time for different surface temperatures set at  $-6^\circ\text{C}$ ,  $-8^\circ\text{C}$  and  
 396  $-9^\circ\text{C}$ . In addition, Figure 14 shows the evolution of the temperature of the surface and of the  
 397 10 wt.% ethanol/water mixture in the surface testing section for different target surface temperatures  
 398 ( $-6^\circ\text{C}$ ,  $-8^\circ\text{C}$  and  $-9^\circ\text{C}$ ).

399

400      **Figure 13** – Growth kinetics of an ice layer up to 2 mm thick on an untreated aluminum surface as a function of time for  
 401      different surface temperatures set at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$  and  $-9\text{ }^{\circ}\text{C}$ .  
 402

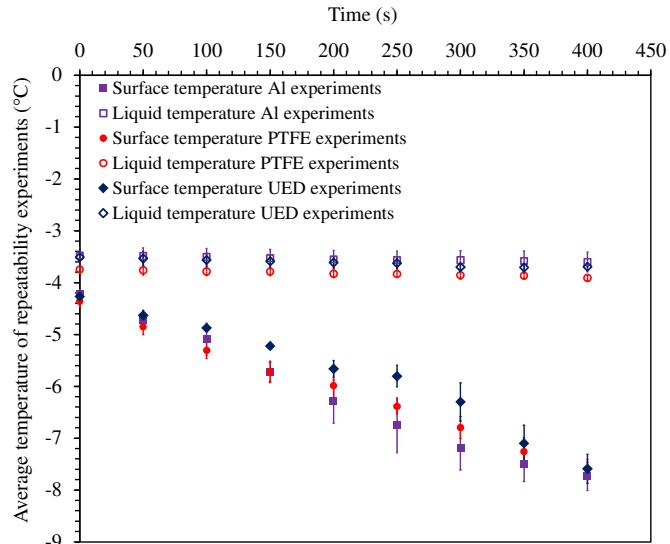

403      **Figure 14** – Evolution of the temperature of the liquid mixture and of the untreated aluminum surfaces during the cooling  
 404      process for three target surface temperatures of  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$  and  $-9\text{ }^{\circ}\text{C}$ .  
 405

406      Figure 13 clearly indicates that a decrease in surface temperature leads to an increase in the ice layer  
 407      growth rate, as the heat flux increases with the decrease in surface temperature. Furthermore, the  
 408      standard deviations for the  $-6\text{ }^{\circ}\text{C}$  case are significant, as shown in Figure 14, because the maximum  
 409      surface temperature is  $-6\text{ }^{\circ}\text{C}$  and the average liquid temperature is  $-3.60\text{ }^{\circ}\text{C}$ . The average temperature  
 410      between the surface and the liquid gives a value close to the phase change temperature, and in this case,  
 411      it is difficult to pass the energy barrier necessary for crystallization. Furthermore, the standard deviation  
 412      of the surface temperature in repeatability experiments is significant. This is due to the formation of an  
 413      ice layer on the surface, which acts as an insulation and therefore causes variability in the surface  
 414      temperature.

### 415      3.2.2 Effect of surface condition on ice growth kinetics

416      Figure 15 shows the analysis of the temperature evolution of the three surfaces: hydrophilic  
 417      (untreated aluminum) as "Al", hydrophobic (aluminum treated with Teflon® coating) as "PTFE", and  
 418      superhydrophobic (aluminum treated with Ultra Ever Dry) as "UED", and the temperature of the  
 419      10 wt.% water-ethanol mixture as a function of time during the surface cooling process. These  
 420      temperatures are plotted for a surface temperature between  $-4.10\text{ }^{\circ}\text{C}$  and a final temperature of  $-8\text{ }^{\circ}\text{C}$ ,  
 421      between which a layer of ice with a maximum thickness of 2 mm is generated. It is observed that the  
 422      temperature variation of the ethanol/water mixture is stable for the three surfaces (Al, PTFE and UED),  
 423      with a standard deviation of less than  $\pm 0.25\text{ }^{\circ}\text{C}$ . Concerning the surface temperature the standard  
 424      deviation does not exceed  $\pm 0.6\text{ }^{\circ}\text{C}$ .

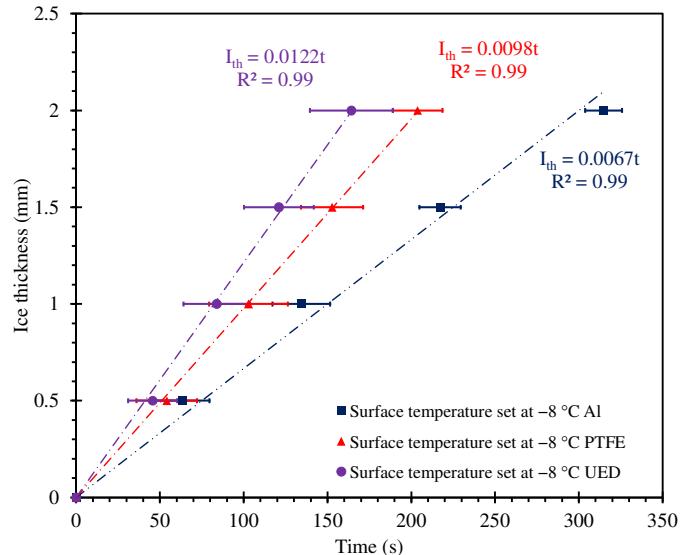

425  
426 **Figure 15** – Evolution of the temperature of the liquid mixture and the three types of surfaces studied during the surface  
427 cooling process.

428 Figure 16 shows the ice growth kinetics as a function of time for the three types of surfaces and for  
429 a target surface temperature of  $-8^{\circ}\text{C}$ . The results indicate that ice growth is faster on the  
430 superhydrophobic UED surface when compared to the PTFE and Al surfaces, even though the surface  
431 temperature of the UED surface is slightly warmer than the others. Additionally, ice growth is slower  
432 on the Al surface when compared to the PTFE surface. The aluminum surface treated with the UED  
433 superhydrophobic coating increases the crystallization rate due to its higher roughness ( $Sa = 12 \mu\text{m}$ , as  
434 described in section 3.1). This value is significantly higher than PTFE ( $Sa = 2.3 \mu\text{m}$  and  $Sa' = 8.4 \mu\text{m}$ )  
435 and untreated aluminum ( $Sa = 0.2 \mu\text{m}$ ), providing more nucleation sites on this superhydrophobic UED  
436 surface. Indeed, roughness contributes to lowering the energy barrier for crystallization, as already  
437 demonstrated in the article by Cao et al. [36]. The authors studied various superhydrophobic coatings  
438 based on nanoparticle-polymer composites with diameters  $D_p = 20 \text{ nm}, 50 \text{ nm}, 100 \text{ nm}, 1 \mu\text{m}$ , and  $20$   
439  $\mu\text{m}$ , with contact angles ranging from  $143^{\circ}$  to  $158^{\circ}$ , and a contact angle hysteresis of  $2^{\circ}$  and  $4^{\circ}$ . The  
440 authors analyzed the effect of nanoparticle size in the superhydrophobic coating on the free energy  
441 barrier. They noticed that the energy barrier for nucleation continuously decreases with an increase in  
442 the size of particles in the superhydrophobic coating (increase in roughness) [36].

443

444

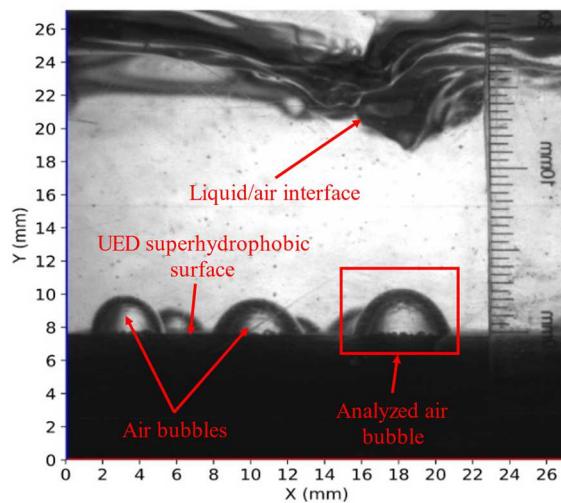

445  
446

**Figure 16** – Ice growth kinetics as a function of time for a target surface temperature of  $-8\text{ }^{\circ}\text{C}$  on the three surface types.

447 However, the PTFE surface has a double roughness due to its texture (glass fiber) of  $Sa'$  about  $8.4\text{ }\mu\text{m}$   
448 and a roughness on the fiber surface ( $Sa = 2.3\text{ }\mu\text{m}$ ). This double roughness also serves as a nucleation  
449 site, explaining why crystallization is faster on the PTFE surface compared to the untreated aluminum  
450 surface, which is characterized by a roughness of  $Sa = 0.2\text{ }\mu\text{m}$ . The surface roughness plays an important  
451 role in influencing the crystallization rate of the ice by providing increasing the surface area available  
452 for crystallization. This leads to a higher crystallization rate due to the increased number of nucleation  
453 sites available for crystals.

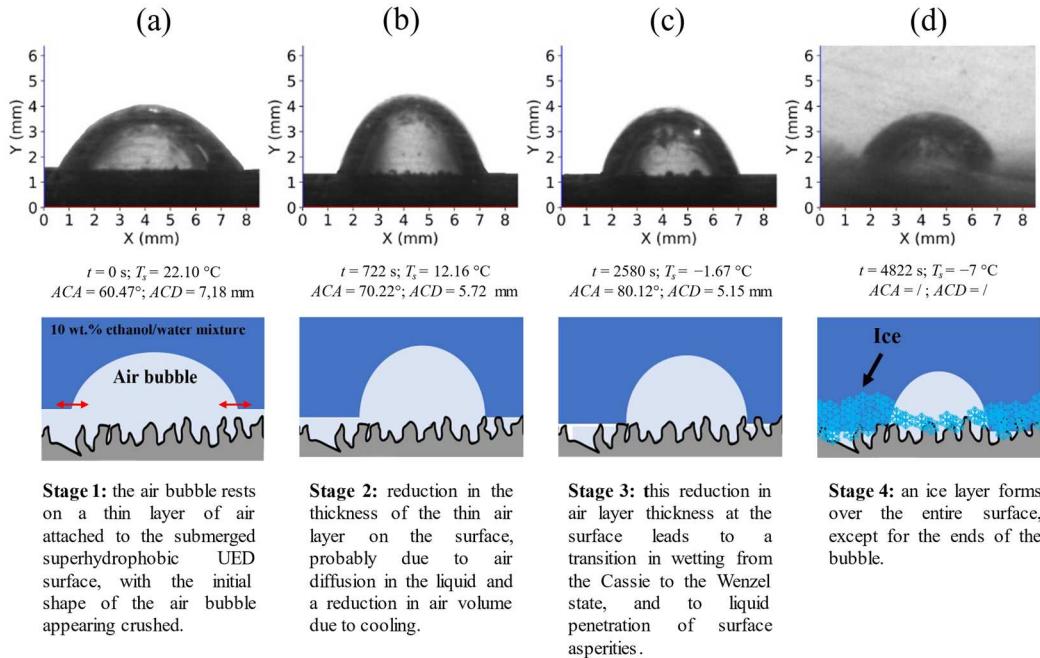

454 The behavior of submerged superhydrophobic surfaces is aerophilic, meaning that they trap air in  
455 their roughness when submerged [37]. Initially, the immersed UED superhydrophobic surface is covered  
456 with a thin layer of air visible as a silvery mirror-like reflection, which is the signature of the presence  
457 of an air layer adhering to the surface. During the cooling process, the silvery mirror reflection becomes  
458 clearer and less reflective (seen by the naked eye), and then disappears when reaching low negative  
459 temperatures ( $-6\text{ }^{\circ}\text{C}$ ). These experiments aim to understand the wetting behavior of the UED  
460 superhydrophobic surface under immersion with surface cooling and understand why the silver mirror  
461 color reflectivity effect that disappears during surface cooling. Figure 17 shows the air bubbles placed  
462 with a pipette on the UED superhydrophobic surface in immersion to verify and understand the physical  
463 phenomena of wetting transition in immersion with surface cooling.

464

465  
466

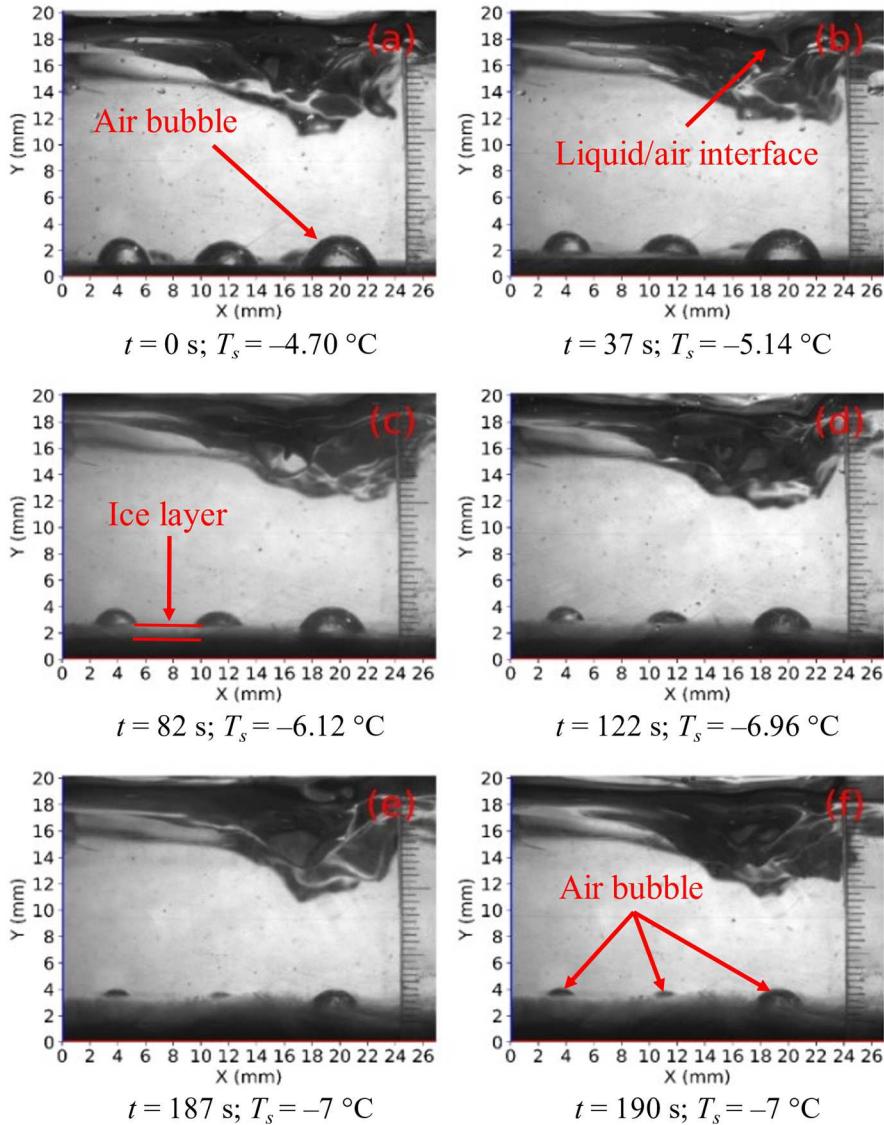

**Figure 17** – Air bubbles deposited on the superhydrophobic UED surface immersed in a 10 wt.% ethanol/water mixture during the cooling process, the surface temperature  $T_s$  is 3.97 °C which corresponds to time  $t = 1622$  s.

467  
468  
469  
470

**Figure 18** – Real image of the air bubble without background and schematic model illustrating the wetting transition on a UED superhydrophobic surface immersed in a 10 wt.% ethanol/water mixture during the surface cooling process.  $T_s$  is the surface temperature, ACA represents the air bubble contact angle, and ACD represents the air bubble contact diameter.

471 Figure 18 shows the real images and a schematic model explaining the behavior of air bubbles and  
472 the wetting transition when immersed in a 10 wt.% ethanol/water mixture on a cooled superhydrophobic  
473 UED surface. This model is considered original because no previous study has verified this wetting  
474 behavior in immersion and at low temperature. When the air bubble is deposited at a temperature of  
475 22.10 °C on the immersed superhydrophobic UED surface, as shown in Figure 18 (a), the initial shape  
476 of the air bubble appears to be squashed. This air bubble has an ACA air contact angle of 60.47° and an  
477 ACD air contact diameter (air bubble base diameter) of 7.18 mm. At this temperature of 22.10°, the air  
478 bubble slides from left to right across the surface due to its contact with the thin layer of air and the  
479 agitation of the mixture caused by the flow. As the surface temperature decreases, the silvery mirror  
480 color becomes less visible, indicating a reduction in the thickness of the thin layer of air on the surface,  
481 likely due to air diffusion into the liquid and a decrease in air volume due to cooling. This decrease in  
482 the thickness of the air layer on the surface leads to a decrease in the contact diameter of the air bubble  
483 (ACD = 5.72 mm) and an increase in its contact angle (ACA = 70.22°) due to buoyancy forces lifting the  
484 bubble vertically, as shown in Figure 18 (b). In the end, a layer of ice forms over the entire surface,  
485 except for the ends of the bubbles which remain in contact with the cooled superhydrophobic surface  
486 due to the lack of contact between the liquid and this cooled surface, as shown in Figure 18 (d). Figure  
487 19 shows the process of ice layer formation on the surface of the UED in the presence of air bubbles.  
488 After the transition from the Cassie wetting state to the Wenzel state, ice forms across the entire surface  
489 except at the locations of air bubbles in immersion, which isolate the liquid from the cold UED surface.

490  
491 **Figure 19** – Formation of a 2 mm ice layer on the UED superhydrophobic surface in a 10 wt.% ethanol/water mixture.

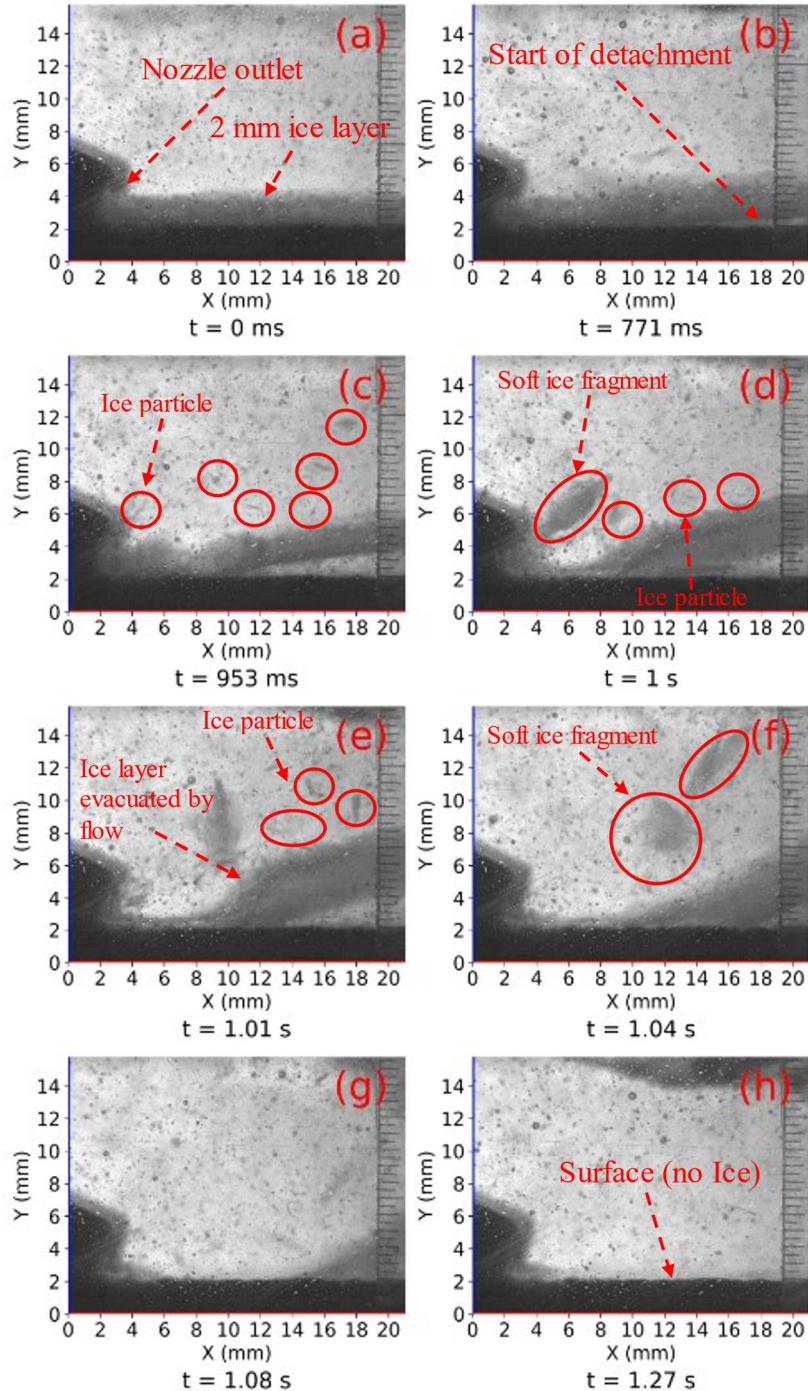

492 **3.3 Ice detachment length evolution**

493 In this subsection, the evolution of  $L_D$  on the three types of surfaces: hydrophilic (untreated  
494 aluminum), hydrophobic (aluminum treated with PTFE adhesive tape), and superhydrophobic  
495 (aluminum treated with a UED superhydrophobic coating) was studied.

496 **3.3.1 Temperature effect on ice detachment length**

497 The experimental results presented in Figure 20 show the detachment of a 2 mm thick ice layer on  
498 an untreated aluminum surface. The surface temperature was set at  $-6^\circ\text{C}$ , and the liquid velocity at the  
499 nozzle outlet ( $V_N$ ), which was oriented horizontally towards the surface, was  $1.62 \text{ m s}^{-1}$ . The detachment  
500 process lasted about 1.27 s, and the type of detachment was identified as adhesive, meaning the ice  
501 detached from the surface without leaving any residue. The ice was characterized as soft, with needle-  
502 like crystals due to the presence of ethanol. After detachment, the ice broke into small particles, as shown  
503 in the images in Figure 20 (c) and 20 (e). Chemical additives have an effect on the morphology of the  
504 ice; for example, seawater (brine) results in porous ice [14,20–22,38]. These additives change the nature  
505 of the ice, making it soft, and the ice crystals often take on the shape of needles, reducing the contact  
506 surface of the ice with the solid surface. If pure water is used to produce the ice, it will have a hard

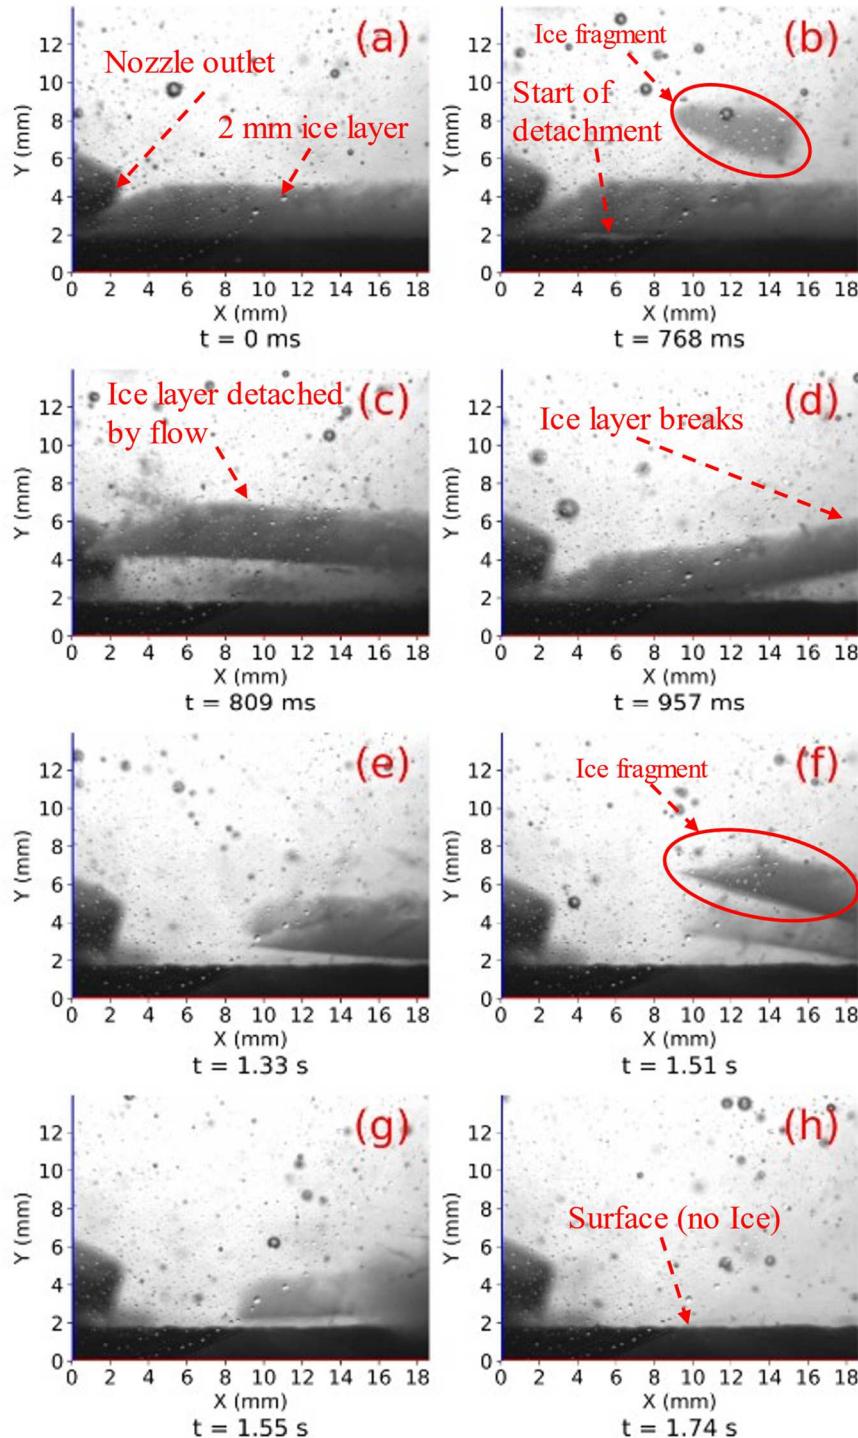

507 texture [22,28]. In the case of a surface temperature set at  $-8^{\circ}\text{C}$ , ice detachment and ice appearance are  
 508 similar to those observed at a surface temperature of  $-6^{\circ}\text{C}$ .

509  
 510 **Figure 20** – Image of ice layer detachment on an untreated aluminum surface for a surface temperature set at  $-6^{\circ}\text{C}$  and an  
 511 average velocity at the nozzle outlet  $V_N$  of  $1.62 \text{ m s}^{-1}$ .

512 Figure 21 shows the results of detaching a 2 mm thick ice layer from an untreated aluminum surface  
 513 at a surface temperature set at  $-9^{\circ}\text{C}$ . The average liquid velocity at the nozzle outlet is  $1.62 \text{ m s}^{-1}$ , which  
 514 is identical to the  $-6^{\circ}\text{C}$  case described earlier. The ice detachment process took approximately 1.74 s,  
 515 slightly longer than in the  $-6^{\circ}\text{C}$  case. As with the  $-6^{\circ}\text{C}$  case, the type of detachment observed was  
 516 adhesive, where the ice layer fully detached from the surface without leaving any residue, as depicted  
 517 in Figures 21 (c)-(f). However, the ice layer does not detach easily, and the ice is hard, in contrast to the  
 518 soft ice observed at  $-6^{\circ}\text{C}$ . The detachment of the ice layer at a temperature of  $-9^{\circ}\text{C}$  occurred in large

519 hard fragments rather than small particles, as shown in Figure 21 (f). This ice hardening is due to the  
 520 effect of low temperature, which accelerates the crystallization process, leading to a densification of the  
 521 ice layer. This effect of temperature has already been observed in a previous study with a 10 wt.%  
 522 aqueous urea solution [22].

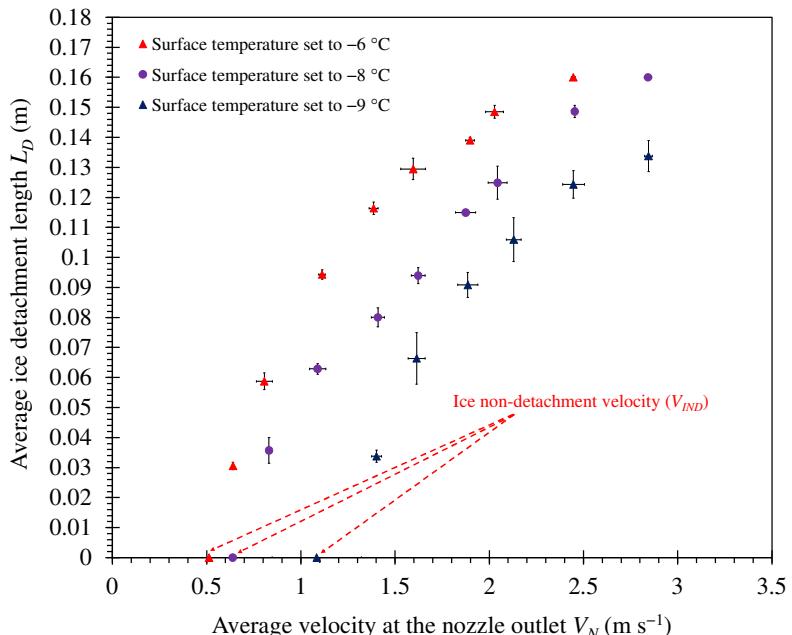

523  
 524 **Figure 21** – Image of ice layer detachment on an untreated aluminum surface for a surface temperature set at  $-9\text{ }^{\circ}\text{C}$  and an  
 525 average velocity at the nozzle outlet of  $1.62\text{ m s}^{-1}$ .

526 Figure 22 shows the variation of the ice detachment length  $L_D$  as a function of the average liquid  
 527 velocity at the nozzle outlet along a 0.16 m long surface. In our experiments, the mass flow rate ranges  
 528 from 0 to  $0.17\text{ kg s}^{-1}$ . This implies a flow velocity at the nozzle outlet ranging from 0 to  $2.87\text{ m s}^{-1}$ . The

529 experiments were conducted on an untreated aluminum surface (hydrophilic) at three different surface  
 530 temperatures ( $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$  and  $-9\text{ }^{\circ}\text{C}$ ). In our experiments, we calculated the flow velocity  $V_N$  at the  
 531 nozzle outlet using the following equation (Eq. 2):

$$V_N = \frac{Q_m}{\rho_l S_N} \quad \text{Eq. (2)}$$

532 Where  $Q_m$  is the mass flow rate,  $\rho_l$  is the density of the mixture, and  $S_N$  is the outlet cross-sectional  
 533 area of the nozzle. As shown in Figure 22, the limit velocity of ice non-detachment  $V_{IND}$ , i.e., the velocity  
 534 below which there is no detachment of ice from the surface, is  $0.51\text{ m s}^{-1}$ ,  $0.64\text{ m s}^{-1}$ , and  $1.08\text{ m s}^{-1}$  for  
 535 surface temperatures set at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$ , and  $-9\text{ }^{\circ}\text{C}$ , respectively. The ice detachment length decreases  
 536 with decreasing surface temperature due to an increase in ice adhesion strength, which is a well-known  
 537 trend in the literature [14,22,39]. At  $-6\text{ }^{\circ}\text{C}$  and  $-8\text{ }^{\circ}\text{C}$ , the required velocity  $V_N$  to detach the ice over the  
 538 entire surface is  $2.45\text{ m s}^{-1}$  and  $2.87\text{ m s}^{-1}$ , respectively. However, for the  $-9\text{ }^{\circ}\text{C}$  surface temperature  
 539 case, the detachment length is limited to  $0.133\text{ m}$ , and the maximum velocity  $V_N$  in our experiments does  
 540 not exceed  $2.87\text{ m s}^{-1}$ , which prevents us from detaching ice along the entire surface length. The standard  
 541 deviations on the  $-9\text{ }^{\circ}\text{C}$  curve are larger due to the production of a hard ice layer (see Figure 21)  
 542 compared to the soft ice layer produced at surface temperatures of  $-6\text{ }^{\circ}\text{C}$  and  $-8\text{ }^{\circ}\text{C}$  (as shown in Figure  
 543 20), resulting in the detachment of large hard fragments from the surface and leading to the variability  
 544 of the detachment length over the three repeatability experiments. An analysis of error propagation for  
 545 measurements of various parameters, such as liquid jet velocities and ice detachment lengths ( $L_D$ ), has  
 546 been conducted. The absolute uncertainties are estimated using the Student's distribution with a 95%  
 547 confidence interval [40]. The measurement errors for liquid jet velocities and ice detachment lengths  
 548 ( $L_D$ ) in Figure 22 are presented in Tables A1, A2, and A3 of Appendix A.

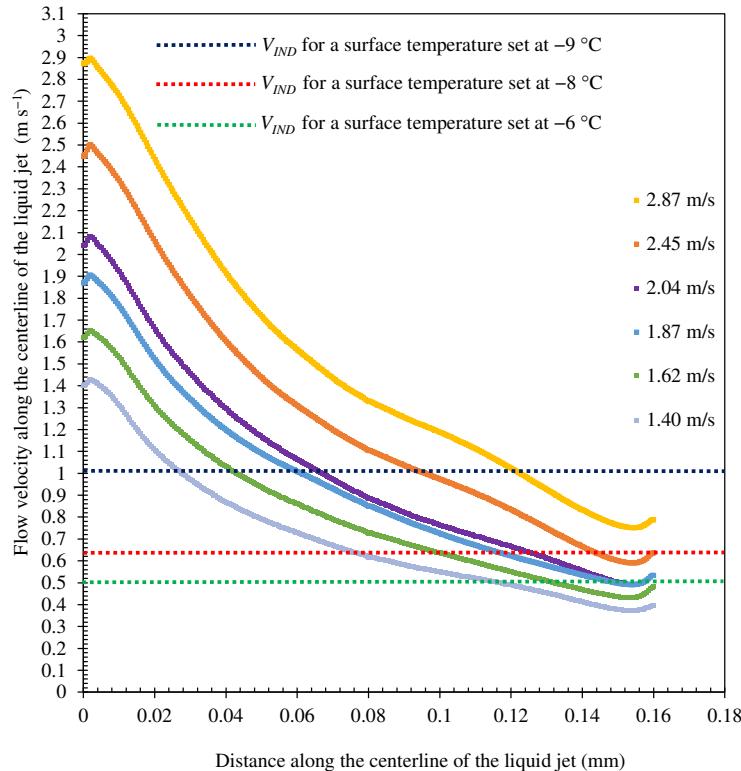

549  
 550 **Figure 22** – Evolution of the ice detachment length  $L_D$  as a function of the average velocity at the nozzle outlet for an  
 551 untreated aluminum surface, for the three surface temperatures set at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$  and  $-9\text{ }^{\circ}\text{C}$ .

### 552 3.3.1.1 Numerical and experimental comparison on the ice detachment length

553 Figure 23 shows the results of ANSYS® Fluent numerical simulations using the numerical method  
 554 described in subsection 2.4. It shows the evolution of the local velocity of the turbulent jet (for flow  
 555 velocities at the nozzle outlet  $V_N$  from  $1.4\text{ m s}^{-1}$  to  $2.87\text{ m s}^{-1}$ ) from the nozzle outlet which is at the  $0\text{ m}$   
 556 position to the  $0.16\text{ m}$  position of the untreated aluminum surface (along the nozzle centerline). The

557 dashed lines represent the limit velocity of ice non-detachment  $V_{IND}$ , determined previously from the  
 558 velocity at the nozzle outlet (see Figure 22), for the cases of surface temperatures set at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$ , and  
 559  $-9\text{ }^{\circ}\text{C}$ , which are  $0.51\text{ m s}^{-1}$ ,  $0.64\text{ m s}^{-1}$ , and  $1.08\text{ m s}^{-1}$ , respectively. The purpose of this numerical  
 560 model is to determine the maximum length,  $L_{Max}$ , for which the local velocity of the liquid jet reaches  
 561 the limit velocity of ice non-detachment  $V_{IND}$ , and compare it with the experimentally ice detachment  
 562 length determined previously,  $L_D$ . According to Figure 23, the local velocity of the jet increases after  
 563 passing through the nozzle outlet due to the decrease in jet pressure, resulting in a slight increase in  
 564 velocity. This velocity then decreases along the jet axis (along the surface). Near the  $0.16\text{ m}$  position,  
 565 there is an increase in velocity due to the discharge outlet (as seen in component 6 of Figure 3), which  
 566 causes a flow acceleration.

567  
 568 **Figure 23** – Evolution of the numerical turbulent velocities of the liquid jet along its centerline for an untreated aluminum  
 569 surface and for the three surface temperatures fixed at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$  and  $-9\text{ }^{\circ}\text{C}$ .

570 Table 3 presents a comparison of the numerical results obtained with ANSYS® Fluent, which show  
 571 the maximum length,  $L_{Max}$ , for which the local velocity of the liquid jet reaches the limit velocity of ice  
 572 non-detachment ( $V_{IND}$ ), and the experimental ice detachment length,  $L_D$ , for the three surface  
 573 temperatures set at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$ , and  $-9\text{ }^{\circ}\text{C}$ .

574  
 575 **Table 3** – Comparison between the maximum numerical length  $L_{Max}$  for which the local velocity of the liquid jet reaches the  
 576 limit velocity of ice non-detachment ( $V_{IND}$ ), and the experimental ice detachment length  $L_D$  at different surface temperatures  
 577 set at  $-6\text{ }^{\circ}\text{C}$ ,  $-8\text{ }^{\circ}\text{C}$  and  $-9\text{ }^{\circ}\text{C}$ .

Velocity at nozzle outlet $V_N$ (m s <sup>-1</sup> )	Reynolds ( $\text{f}$ )	Surface temperature $-6\text{ }^{\circ}\text{C}$		Surface temperature $-8\text{ }^{\circ}\text{C}$		Surface temperature $-9\text{ }^{\circ}\text{C}$	
		$L_{Max}$ NUM (m)	$L_D$ EXP (m)	$L_{Max}$ NUM (m)	$L_D$ EXP (m)	$L_{Max}$ NUM (m)	$L_D$ EXP (m)
2.87	5545	0.16	0.16	0.16	0.16	0.114	0.133
2.45	4783	0.16	0.16	0.144	0.148	0.083	0.124
2.04	3983	0.146	0.148	0.126	0.124	0.058	0.105
1.87	3651	0.144	0.139	0.117	0.114	0.05	0.09

1.40	2733	0.113	0.116	0.077	0.080	0.021	0.033

578

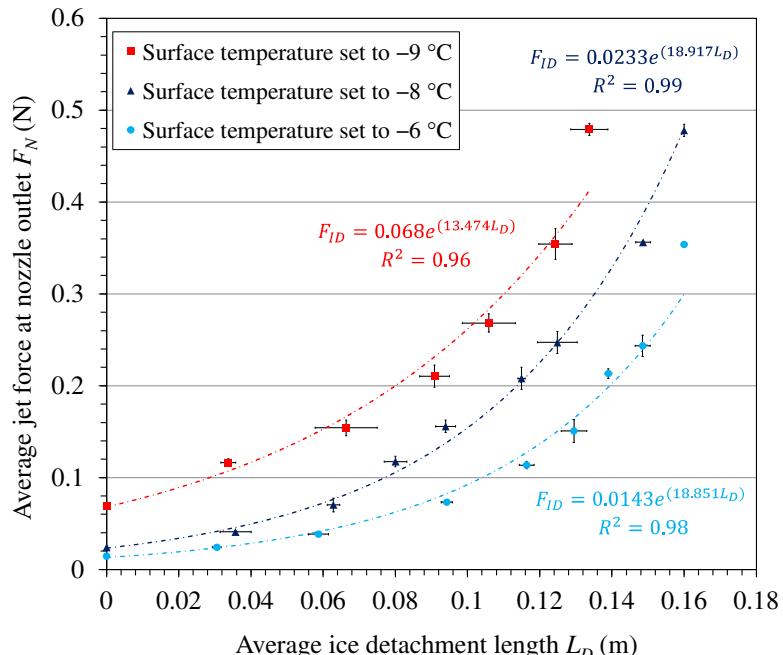

579 It can be seen in Table 3 that the relative differences between the  $L_{Max}$  lengths of the numerical  
 580 simulations (NUM) and the  $L_D$  lengths of the experimental results (EXP) for the case of surface  
 581 temperatures set at  $-6$   $^{\circ}\text{C}$  and  $-8$   $^{\circ}\text{C}$ , are not significant, i.e. with a maximum difference (relative  
 582 deviation) less than 8%, which indicates the validation of our numerical model for the case of these two  
 583 surface temperatures. Indeed, the positions found numerically for which the local velocity of the liquid  
 584 jet reaches the ice non-detachment velocity ( $V_{IND}$ ) are very close to the ice detachment positions found  
 585 experimentally. This can be explained by the fact that in these two cases of surface temperature fixed at  
 586  $-6$   $^{\circ}\text{C}$  and  $-8$   $^{\circ}\text{C}$ , the ice produced and detached is soft and the detachment stops at the position where  
 587 the liquid jet velocity reaches the ice non-detachment velocity. However, for the case of the surface  
 588 temperature fixed at  $-9$   $^{\circ}\text{C}$  (see Table 3), the relative deviations are very large, above 8%. In this case  
 589 the numerical model is not able to predict the position of the ice non-detachment velocities because in  
 590 this case the ice detaches in large hard fragments in a less repeated way, which results in a very high  
 591 relative deviation. Therefore, our numerical model is only valid in the case where the detached ice is  
 592 soft for the  $-6$   $^{\circ}\text{C}$  and  $-8$   $^{\circ}\text{C}$  surface temperature cases.

### 593 3.3.1.2 Evaluation of liquid jet force on ice detachment

594 In this part, an evaluation of the liquid jet force is presented along with an empirical model to estimate  
 595 the effect of this force on the evolution of the ice detachment length  $L_D$  on the untreated aluminum  
 596 surface for the three surface temperatures set at  $-6$   $^{\circ}\text{C}$ ,  $-8$   $^{\circ}\text{C}$ , and  $-9$   $^{\circ}\text{C}$ . The force of the jet at the  
 597 nozzle outlet  $F_N$  can be calculated using the following equation (Eq.3):

$$598 F_N = Q_m V_N = \rho_l S_N V_N^2 = 2P_D S_N \quad \text{Eq. (3)}$$

598 Where  $\rho_l$  is the density of the fluid,  $Q_m$  is the mass flow rate at nozzle outlet,  $S_N$  is the nozzle outlet  
 599 cross-section,  $P_D = 0.5\rho_l V_N^2$  is the dynamic pressure at the nozzle outlet, and  $V_N$  is the flow velocity at  
 600 the nozzle outlet.

601  
 602 **Figure 24** – Evolution of the jet force at the nozzle outlet for ice detachment  $F_{ID}$  as a function of the ice detachment length  
 603  $L_D$  for an untreated aluminum surface and this for the three cases of surface temperature fixed at  $-6$   $^{\circ}\text{C}$ ,  $-8$   $^{\circ}\text{C}$  and  $-9$   $^{\circ}\text{C}$ .

604 Figure 24 shows the liquid jet force at the nozzle outlet as a function of the ice detachment length  
 605 obtained with equation (Eq.3) for the case of the untreated aluminum surface with surface temperature

606 variation. It can be observed that the force of the liquid jet at the nozzle outlet for ice detachment  $F_{ID}$   
 607 (Force Ice Detachment) varies with the ice detachment length and has an exponential curve. Using this  
 608 curve, a force model of the form shown in Equation (Eq.4) is obtained:

$$F_{ID} = F_0 \exp(kL_D) \quad \text{Eq. (4)}$$

609 Where  $F_0$  represents the force below which there is no ice detachment,  $L_D$  the ice detachment length  
 610 which varies between 0 and 0.16 m, and  $k$  a constant that depends on several experimental parameters  
 611 such as surface temperature, immersion level, jet force dissipation, and configuration geometry. This  
 612 model provides minimum force  $F_0$  values required for ice detachment, as well as maximum values  $F_{Max}$   
 613 for full surface ice detachment, for each temperature, as shown in Table 4:

614 **Table 4** – Minimum, maximum force for ice detachment for each investigated surface temperature.

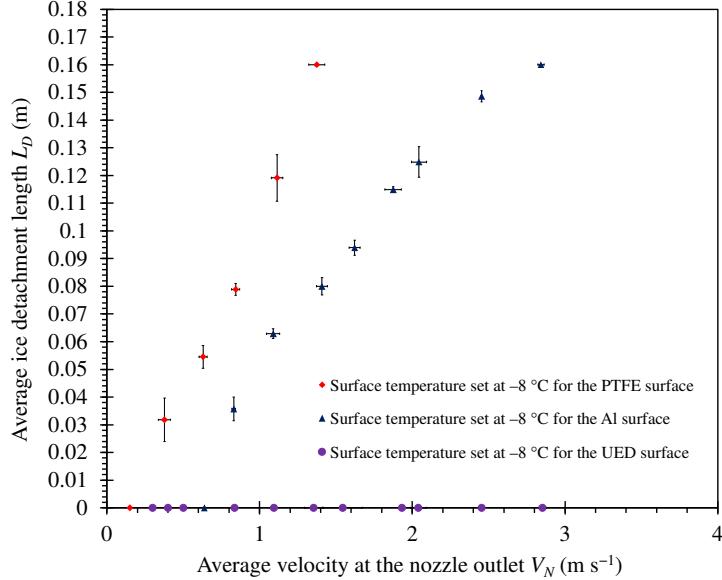

Temperature (°C)	Minimum forces $F_0$ (N)	Minimum velocities $V_0$ ( $V_{IND}$ ) (m s <sup>-1</sup> )	Maximum forces $F_{Max}$ (N)	Maximum velocities $V_{Max}$ (m s <sup>-1</sup> )	$L_D$ EXP (m)
- 6	0.014	0.51	0.35	2.44	0.16
- 8	0.023	0.64	0.48	2.84	0.16
- 9	0.068	1.08	0.48	2.84	0.133

615 Table 4 shows that the force required to detach the ice from the entire surface of the untreated  
 616 aluminum samples is 0.35 N, when the surface temperature is set at - 6 °C, and 0.48 N when the surface  
 617 temperature is set at - 8 °C and - 9 °C. This low force is due to the porosity of the ice layer which reduces  
 618 the adhesion of the ice to the surface, which may be caused by the presence of ethanol in the aqueous  
 619 mixture.

620 As the surface temperature decreases, the force required to detach the ice increases, due to the  
 621 hardness of the ice and its strong adhesion. It is difficult to compare these experimental forces with  
 622 literature results [41–43]. Several factors, such as the presence of microcracks, roughness, quasi-liquid  
 623 micro-layers, etc., affect the adhesion of ice to the surface [14]. Furthermore, this study focuses on the  
 624 adhesion of ice produced with a water-ethanol mixture, which reduces the adhesion force of the ice to  
 625 the surface. Indeed, the nature of ice differs from that of pure water. The presence of ethanol makes the  
 626 ice softer and more porous, even causing the formation of needle-shaped crystals, which reduces its  
 627 contact with the surface and, consequently, its adhesion. A critical review of the development of a  
 628 common standard for ice adhesion and different methods of measuring ice adhesion forces was  
 629 published by Rønneberg et al. [39]. The authors suggest that the measured adhesion forces are very  
 630 sensitive to both the measurement method and the ice type.

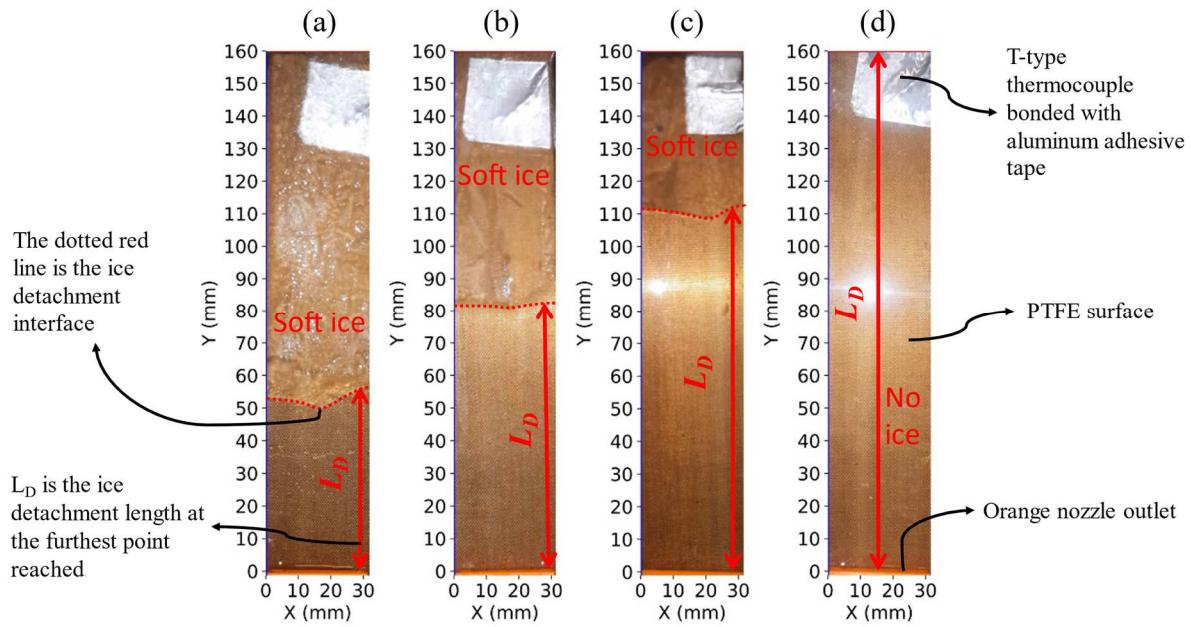

### 631 3.3.2 *Surface condition effect on ice detachment length*

632 In Figure 25, the experimental results are presented for comparing the evolution of the detachment  
 633 length of the 2 mm thick ice layer ( $L_D$ ) as a function of the average velocity at the nozzle outlet  $V_N$  for a  
 634 surface temperature fixed at - 8 °C. The results are presented for all three surface samples. Error  
 635 propagation analysis was performed to assess absolute uncertainties, using Student's distribution with a  
 636 95% confidence interval [40]. The resulting measurement errors for liquid jet velocities and ice  
 637 detachment lengths ( $L_D$ ), shown in Figure 25, are documented in Tables B1 and B2 in Appendix B.

638  
639 **Figure 25** – Evolution of the ice detachment length  $L_D$  as a function of the average velocity of the aqueous mixture at the  
640 nozzle outlet  $V_N$  for three types of investigated samples: untreated aluminum "Al" (hydrophilic), aluminum treated with a  
641 Teflon® tape "PTFE" (hydrophobic), and aluminum treated with the Ultra Ever Dry coating "UED" (superhydrophobic).

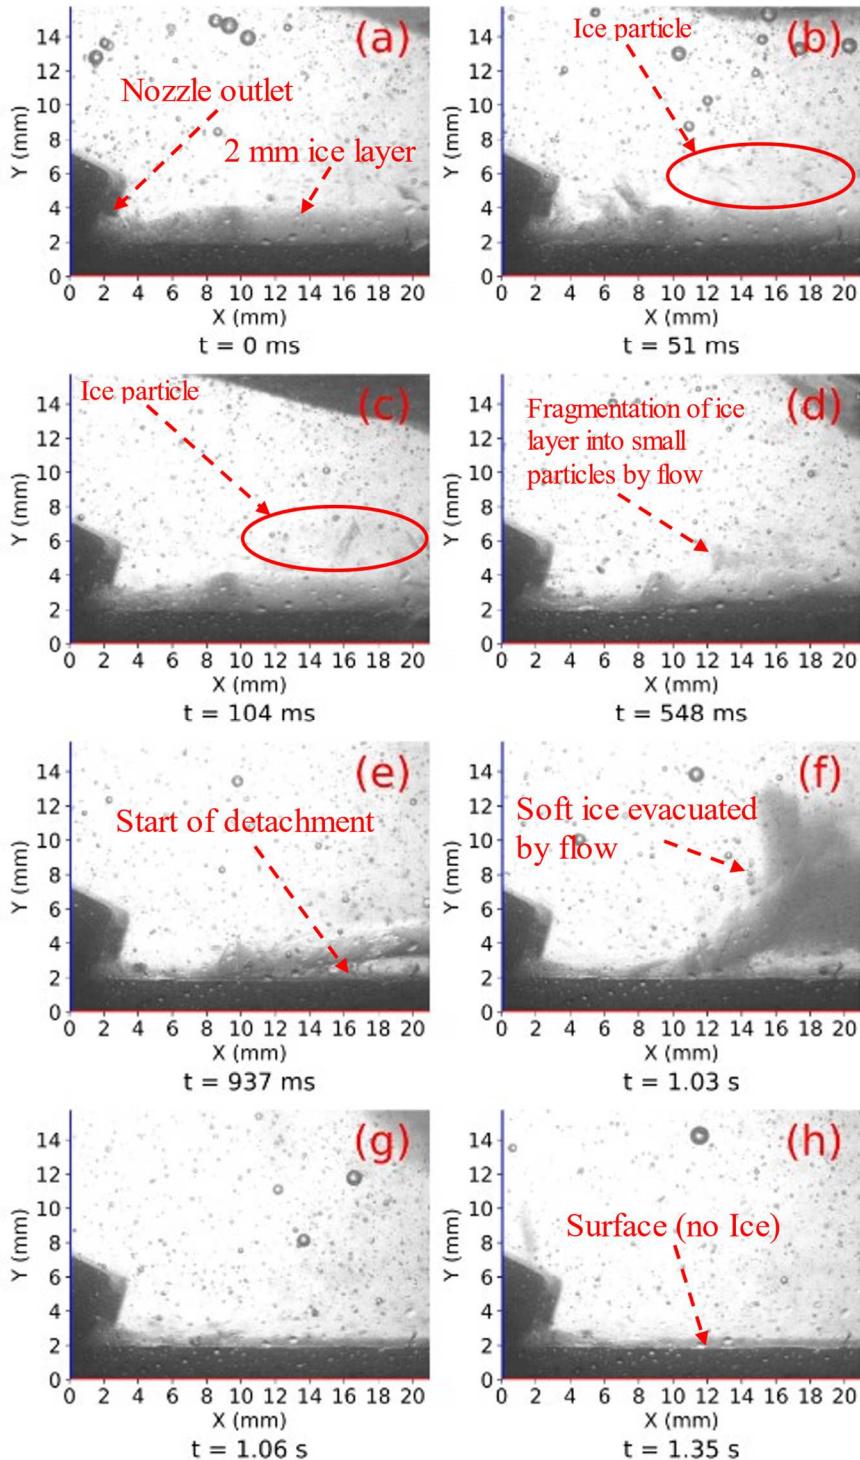

642 In Figure 25, it can be observed that there is no visible ice layer detachment on the aluminum surface  
643 treated with the UED superhydrophobic coating, as shown in Figure 28, for all flow velocities studied.  
644 This result is consistent with the data published in the literature, which indicates that superhydrophobic  
645 surfaces do not reduce ice adhesion [41,44]. This is due to the transition from the Cassie state to the  
646 Wenzel state, resulting in mechanical interlocking, as demonstrated by Chen et al. [41]. The explanation  
647 for this result is the effect of the high roughness of the UED superhydrophobic surface, which is  
648 characterized by the roughness parameter  $Sz$  of 83.4  $\mu\text{m}$ , as described in subsection 3.1. This value is  
649 significantly higher than that of PTFE (18.9  $\mu\text{m}$ ) and untreated aluminum (1.3  $\mu\text{m}$ ). The increase in  
650 surface roughness leads to an increase in the contact area and the number of potential anchor sites for  
651 the ice layer [45]. Four mechanisms can explain the phenomenon of ice adhesion to a surface, as  
652 described in a review article published by Samah et al. [14]: the mechanical mechanism, the chemical  
653 mechanism, the electrostatic mechanism, and the boundary layer mechanism [46–48]. For the case of  
654 the untreated (hydrophilic) aluminum surface, it is noted that there is no visible ice detachment on the  
655 surface below a velocity  $V_{IND}$  of 0.64  $\text{m s}^{-1}$ . To detach all the ice along the 160 mm (0.16 m) exchanger,  
656 a velocity  $V_N$  of 2.87  $\text{m s}^{-1}$  is required. On the aluminum surface treated with PTFE adhesive ribbon, the  
657 limit velocity of ice non-detachment  $V_{IND}$  is equal to 0.15  $\text{m s}^{-1}$ , which is four times less than the limit  
658 velocity of ice non-detachment  $V_{IND}$  on the untreated aluminum surface. To detach all the ice along the  
659 heat exchanger, a velocity  $V_N$  of about 1.37  $\text{m s}^{-1}$  is required (see Figure 26 (d)), which is half that of the  
660 untreated aluminum surface, although the roughness parameter  $Sz$  of PTFE, which is 18.9  $\mu\text{m}$ , is much  
661 higher than that of the untreated aluminum surface, which is about 1.3  $\mu\text{m}$ . This result indicates that  
662 Teflon® (PTFE) exhibits good ice-repellent characteristics (low ice adhesion) compared to the untreated  
663 aluminum surface (hydrophilic) and the UED treated aluminum surface (superhydrophobic). This result  
664 is consistent with the results of Brooks et al. [20,21], and the results of ice adhesion tests on Teflon®  
665 (PTFE) by Fillion et al. [49]. PTFE is currently one of the best icephobic materials reducing ice adhesion  
666 forces due to its low dielectric permittivity of about  $\approx 2.1$  [50]. In conclusion, the use of a Teflon®  
667 (PTFE) coating or tape for ice slurry generation will reduce the amount of energy required to detach the  
668 ice from the surface, provided that the Teflon® coating or tape is thin enough to not penalize heat transfer.

669  
670 **Figure 26** – Example of 4 experiments of the measurement of the ice detachment length " $L_D$ " (m) for the case of an  
671 aluminum surface treated with the PTEF adhesive ribbon for a surface temperature fixed at  $-8$  °C: (a)  $V_N = 0.64$  m s<sup>-1</sup> and  
672  $L_D = 0.057$  m; (b)  $V_N = 0.86$  m s<sup>-1</sup> and  $L_D = 0.083$  m; (c)  $V_N = 1.08$  m s<sup>-1</sup> and  $L_D = 0.113$  m; (d)  $V_N = 1.41$  m s<sup>-1</sup> and  
673  $L_D = 0.16$  m.

674 In order to illustrate the icephobic behavior of Teflon® (PTFE), Figure 26 presents the evolution of  
675 the ice detachment length ( $L_D$ ) on the aluminum surface treated with Teflon® (PTFE) ribbon for different  
676 flow velocities and a fixed surface temperature of  $-8$  °C. The measurement of the ice detachment length  
677 is taken at the point of maximum detachment. It can be seen in this figure that the area where the ice is  
678 detached has no ice residue (see also Figure 27), which is consistent with adhesive detachment. The  
679 detached ice is soft (needle-like crystals), allowing it to disintegrate into large fragments into particles  
680 under the effect of the flow agitation.

687  
688  
689

**Figure 27** – Image of the ice layer detachment on an aluminum surface treated with PTFE ribbon for a set surface temperature of  $-8^{\circ}\text{C}$  and an average nozzle exit velocity of  $2 \text{ m s}^{-1}$ .

690 The high-speed camera images in Figures 27 and 28 show the ice layer detachment on the aluminum  
691 surface treated with PTFE adhesive tape and on the aluminum surface treated with Ultra Ever Dry  
692 "UED" coating, respectively, for a flow velocity of  $2 \text{ m s}^{-1}$ .

693 As shown in Figure 27, the detachment of the ice from the PTFE surface is adhesive, i.e., the entire  
694 ice layer detaches from the surface without leaving any ice residue. This ice layer is soft, so it  
695 disintegrates into ice particles under the agitation of the flow. After 1.35 seconds, the entire ice layer

696 detaches from the PTFE surface. The ice detaches in the same way on the untreated aluminum surface  
697 with adhesive detachment.

698  
699 **Figure 28** – Image of the ice layer detachment on an aluminum surface treated with UED superhydrophobic coating for a set  
700 surface temperature of  $-8\text{ }^{\circ}\text{C}$  and an average nozzle exit velocity of  $2\text{ m s}^{-1}$ .

701 In the case of the aluminum surface treated with UED superhydrophobic coating, no adhesive  
702 detachment was observed on the surface for all flow velocities studied (see Figure 25). This is due to  
703 the roughness of the UED superhydrophobic surface, which is much greater than that of the PTFE-  
704 treated (hydrophobic) or untreated (hydrophilic) aluminum surfaces, as previously explained. However,

705 after 9.91 seconds, a reduction in ice thickness was observed near the nozzle outlet due to ice crystal  
706 breakup within the ice layer (see Figure 28). This type of ice breakup is referred to as cohesive  
707 detachment, as the ice does not completely detach from the surface. Notably, the aluminum surface  
708 treated with the UED superhydrophobic coating exhibited higher ice adhesion compared to the  
709 aluminum treated with PTFE adhesive tape (hydrophobic) and untreated (hydrophilic).

## 710 **4. Conclusions and outlook**

711 In conclusion, this study aimed to understand the adhesion and detachment mechanisms of a 2 mm  
712 thick ice layer on different surfaces (hydrophilic, hydrophobic, and superhydrophobic) using a liquid jet  
713 with variable speeds under immersion conditions in a 10 wt.% ethanol/water mixture. The ultimate goal  
714 was to develop a method of ice slurry production without the need for mechanical scrapers. The key  
715 findings and implications of the study are summarized as follows:

- 716 1. Surface Temperature and Ice Growth: The study observed that the growth rate of the ice  
717 layer increased as the surface temperature decreased. Notably, the nature of the ice produced  
718 at different temperatures (-6 °C, -8 °C, and -9 °C) exhibited variations, with softer ice  
719 forming at -6 °C and -8 °C, which can easily disintegrate into ice particles, and harder ice  
720 forming at -9 °C, which is more resistant to disintegration into ice particles.
- 721 2. Surface Roughness and Ice Growth: The research revealed that increasing surface roughness  
722 created more nucleation sites, resulting in faster ice growth rates. Specifically, the  
723 superhydrophobic surface treated with UED exhibited the fastest ice growth, followed by the  
724 surface treated with PTFE, while the untreated aluminum surface showed the slowest  
725 growth.
- 726 3. Adhesion and Detachment Mechanisms: Surface roughness is a key factor influencing ice  
727 adhesion, as higher roughness leads to stronger mechanical adhesion of ice to surfaces.  
728 However, the case of aluminum surfaces treated with PTFE adhesive ribbon shows lower ice  
729 adhesion due to its low dielectric constant. The jet velocities required for soft ice detachment  
730 on the entire PTFE surface are two times lower than on untreated aluminum surfaces. This  
731 indicates that PTFE exhibits effective icephobic properties, reducing ice adhesion compared  
732 to untreated aluminum surfaces and those treated with superhydrophobic UED.
- 733 4. Modes of ice detachment: Adhesive detachment on low-roughness surfaces (untreated  
734 aluminum and PTFE adhesive tape-treated surfaces). Cohesive detachment on rougher  
735 surfaces, such as aluminum surfaces treated with UED superhydrophobic coating.

736 From a comprehensive perspective, applying a PTFE coating or adhesive ribbon to the ice slurry  
737 generator can reduce the energy required to remove ice from a surface. However, further investigation  
738 is needed to assess the durability and resistance of these coatings under low-temperature immersion  
739 conditions, especially when used in ice slurry generators for the food sector to ensure food safety.  
740 Moreover, future studies should examine ice adhesion on different surfaces using various methods such  
741 as centrifugation or shear, incorporating different mixtures to evaluate the effect of additives like ethanol  
742 and glycol in water on the nature of ice and its adhesion to surfaces.

## 743 **Acknowledgements**

744 The authors would like to thank the National Research Institute for Agriculture, Food, and the  
745 Environment (INRAE) and De Vinci Research Center (DVRC) for their financial support of ice slurry  
746 research.

900 **Appendix A:** Measurement uncertainty of liquid jet velocity and ice detachment  
 901 length ( $L_D$ ) for the case of untreated aluminum surface.

902 The data related to the liquid jet velocity and ice detachment length ( $L_D$ ) from Figure 22,  
 903 which represents the evolution of the average ice detachment length  $L_D$  as a function of the  
 904 average velocity at the nozzle outlet in the case of an untreated aluminum surface, are detailed  
 905 in Tables A1, A2, and A3, along with their absolute uncertainties. The data are provided for  
 906 each studied surface temperature ( $-6\text{ }^\circ\text{C}$ ,  $-8\text{ }^\circ\text{C}$ , and  $-9\text{ }^\circ\text{C}$ ).

907 **Table A.1:** *Absolute uncertainties of the measurements of liquid jet velocities and ice detachment*

# Context

Scraped surface generators are the most commonly used in the refrigeration industry for ice slurry production.

These scraped surface ice slurry generators have drawbacks due to the adhesive strength of the ice:

- ❖ Excessive consumption of additional mechanical energy.
- ❖ High investment costs.
- ❖ Wearing out of the scrapers.

## Reduction of ice adhesion for optimization of ice slurry generators

- ❖ Use of additives to form a soft, porous ice layer to reduce ice adhesion.
- ❖ Surface modification: reduction of roughness and/or use of low surface energy coatings to reduce the adhesion force of the soft ice to the generator surface and facilitate its detachment only by liquid flow (hydro scraping).
- ❖ Use of an intermittent liquid jet to detach the soft ice layer after the formation of a thin layer of 1 to 2 mm.
