Abstract 14

Noise plays a major role in cellular processes and in the development of tissues and organs. 15 Several studies have examined the origin, the integration or the accommodation of noise in 16 gene expression, cell growth and elaboration of organ shape. By contrast, much less is known 17 about variability in cell division plane positioning, its origin and links with cell geometry, and 18 its impact on tissue organization. Taking advantage of the first-stereotyped-then-variable divi-19 sion patterns in the embryo of the model plant Arabidopsis thaliana, we combined 3D imaging 20 and quantitative cell shape and cell lineage analysis together with mathematical and computer 21 modeling to perform a large scale, systematic analysis of variability in division plane orienta-22 tion. Our results reveal that, paradoxically, variability in cell division patterns of Arabidopsis 23 embryos is accompanied by a progressive reduction of cell shape heterogeneity. The paradox 24 is solved by showing that variability operates within a reduced repertoire of possible division 25 plane orientations that is related to cell geometry. We show that in several domains of the em-26 bryo, a recently proposed geometrical division rule recapitulates observed variable patterns, 27 thus suggesting that variable patterns emerge from deterministic principles operating in a vari-28 able geometrical context. Our work highlights the importance of emerging patterns in the plant 29 embryo under iterated division principles, but also reveal domains where deviations between 30 rule predictions and experimental observations point to additional regulatory mechanisms. 31

Introduction 1 32

55

In multicellular organisms, cell division is one of the major mechanisms that subtend the elab-33 oration and maintenance of functional tissue organizations, as observed for example in animal 34 epithelia (Lemke and Nelson, 2021). In plants, division is the primary determinant of relative 35 cell positions because the cellular wall forbids cell displacements and intercalations (Fowler 36 and Quatrano, 1997). Deciphering the principles that underlie the positioning and orientation 37 of division plane is thus a central question to understand organ development and morphogen-38 esis (Gillies and Cabernard, 2011). The possibility that universal primary physical principles 39 operate in cleavage plane selection has led to the formulation of several geometrical rules re-40 lating division plane positioning to mother cell shape (Minc and Piel, 2012), such as Errera's 41 rule of plane area minimization for cells dividing symmetrically (i.e., producing daughters of 42 approximately identical sizes) (Errera, 1888). Though they are essentially phenomenological, 43 such rules have proved useful as proxys to highlight generic cellular mechanisms that may be 44 shared between cells with varying morphologies. 45

Stochastic fluctuations, or noise, play a major role in developmental systems (Meyer and 46 Roeder, 2014; Cortijo and Locke, 2020). For example, at the molecular level, transcriptional 47 noise has been recognized as a source of heterogeneity in cell fates (Meyer et al., 2017); at 48 the cellular level, noise in growth rate has been suggested to contribute to the robustness in 49 the development of organ size and shape (Hong et al., 2016); at higher levels, it has been 50 proposed that stochastic fluctuations could subtend plant proprioception up to the organ and 51 organism scales (Moulia et al., 2021). However, in contrast with variability and heterogeneity 52 in cell and tissue growth, stochasticity in the positioning of the cell division plane has received 53 much less attention. A noticeable exception is the seminal work of Besson and Dumais, who 54 showed that in several two-dimensional plant systems with symmetric divisions, a stochastic

formulation of Errera's rule accounted better for observed division patterns than its determin-56 istic counterpart (Besson and Dumais, 2011). In addition, the impact on tissue organization 57 of deterministic and variable division rules has been examined from a statistical point of view 58 (Gibson et al., 2006; Sahlin and Jönsson, 2010; Alim et al., 2012; Wyatt et al., 2015) but 59 the combinatorics of cell patterns (possible spatial arrangements of cells) that can result from 60 variable cell divisions has not been examined with a cellular resolution. Overall, systematic 61 analyses of variability in division plane positioning and of its relations to cell shape and tissue 62 topological organization are currently lacking. 63 Here, we used the embryo in the model plant Arabidopsis thaliana to fill this gap, taking ad-64 vantage of the variable cell division patterns observed in this system after initial rounds of 65 completely stereotyped cell divisions (Mansfield and Briarty, 1991; Capron et al., 2009). We 66 combined 3D image analysis, cell lineage reconstruction, and computer modeling to systemat-67 ically dissect the spatio-temporal diversity of cell shapes and cell divisions and to challenge the 68 existence of a possible geometrical rule linking cell geometry and division plane positioning. 69 Paradoxically, our quantifications revealed that cell shapes resulting from variable cell divisions 70 were evolving within a restrained repertoire of possibilities, highlighting the existence of hidden 71 geometrical constraints behind the apparent variability of division patterns. We tracked the ori-72 gin of these constraints back to the mother cell geometry and show that most of the observed 73 patterns could be interpreted in light of a recently proposed division rule relating cell shape 74 and plane positioning (Moukhtar et al., 2019). Our results reveal a unifying principle behind 75 stereotyped and variable cell divisions in Arabidopsis early embryo, suggesting stochasticity 76

is an emergent property of the evolution of cell shapes during the first generations of cell di-

visions. Cases where observed patterns deviate from the rule illustrate how our model can

⁷⁹ highlight domains where, beyond cell geometry, additional regulators may be involved in the

⁸⁰ positioning of the division plane.

81 2 Results

⁸² In *Arabidopsis thaliana*, the fourth round of cell division leads to a 16-cell (16C) embryo where ⁸³ four different domains can be distinguished based on their longitudinal (apical or basal) and ⁸⁴ radial (inner or outer) location (Figure 1A). The first four rounds of cell divisions follow invariant ⁸⁵ patterns, which can be predicted based on cell geometry (Moukhtar et al., 2019). Hence, 16C ⁸⁶ embryos exhibit cell shapes that are specific to each of the four domains (Moukhtar et al., ⁸⁷ 2019) and present invariant, symmetrical radial cell organizations in both the apical and the ⁸⁸ basal domains (Figure 1BC).

Here, we examined whether the stereotypical nature of cell shapes and patterns was main-89 tained during late embryo development within each domain. We analyzed cell shapes and cell 90 patterns over ~100 embryos between 1C and 256C stages (rounds 1 to 8 of cell divisions from 91 the 1C stage). In accordance with previous observations (Yoshida et al., 2014), we initially ob-92 served that, from generation 5 onwards, the basal part of the embryo showed little variability in 93 cell shapes and spatial arrangements, leading to a preserved radial symmetry across domains 94 and individuals (Figure 1DE). On the contrary, shapes and arrangements of cells were highly 95 variable in the apical domain. Different orientations and topologies of cell divisions were ob-96 served among the different quarters in a given individual as well as among different individuals 97 (Figure 1DE). This variability resulted in a loss of radial symmetry of cell organization in the 98

apical domain (Figure 1DE). To better characterize and understand the origin of this variability,
 we conducted an in-depth quantitative analysis and modeling study of cell shapes and division
 patterns.

¹⁰² 2.1 Diversity in cell shape is domain-specific

To quantitatively describe cell patterns, we first focused on the diversity of cell shape in the em-103 bryo and in its four principal domains defined from the 16C stage (apical/basal \times inner/outer). 104 For each embryo, cells were segmented in 3D and their lineage reconstructed back to the 105 1C stage by recursively merging sister cells (Figure 2A). To allow the classification of cells 106 into different shape categories, we focused on shape topology rather than on exact geometry 107 provided by cell segmentation. Shape topology corresponds to the morphological informa-108 tion that remains unchanged under position, orientation, scale or other linear and non-linear 109 geometrical transformations such as anisotropic scaling, shearing, and bending. Distinguish-110 ing topology from geometry is important when analyzing the variability of cell patterns since 111 cells with different geometries can be produced even under invariant orientations of cell divi-112 sions. For example, cells in the inner apical domain at the 16C stage can all be described as 113 tetrahedral pyramids even though none of these cells have the same geometry (Figure 1BC). 114

We introduced a new cell shape topology descriptor based on the cumulative number of di-115 vision planes that were positioned through generations to generate a given cell (Figure 2B). 116 This number, referred to as the number of faces, was automatically computed from cell lin-117 eages reconstructed back to the initial 1C stage, which contains two faces (see Material and 118 Methods). A key advantage of this descriptor is to provide a robust, objective and unambigu-119 ous description of cell shape. Contrary to the number of neighboring cells or to the number of 120 geometrical facets, the number of division faces only depends on the topology of cell divisions 121 and is insensitive to geometrical fluctuations in the positioning of division planes and to their 122 curvature. 123

We first applied this descriptor to analyze cell shapes up to the 16C stage (Figure 2C). The 124 truncated sphere and half-sphere cell shapes of stages 1C and 2C have two and three-face 125 shapes, respectively. The truncated sphere quarter at 4C has four division faces and is thus 126 topologically equivalent to a tetrahedron. At stage 8C, the apical cells also have four faces 127 but a new shape type is observed in the basal domain where cells have five faces, thus being 128 topologically equivalent to a prism with a triangular basis. At stage 16C, a new cell shape 129 with six faces was observed, being topologically equivalent to a cuboid. For each of the first 130 four generations, each embryo domain (one domain from 1C to 4C, two domains at 8C, four 131 at 16C) contained exactly one cell shape. These results are consistent with the stereotyped 132 nature of cell division patterns until 16C stage. In addition, our analysis shows that at the whole 133 embryo scale each generation corresponded to the introduction of a new cell shape with a unit 134 increase in the number of division faces. 135

Over the next four generations (G5 to G8), we found that more than 99% embryonic cell shapes were distributed over the three main cell topologies already present at stage 16C, corresponding to shapes with four (3.6%), five (21.9%) and six (73.7%) faces (Figure 2D). From generation 4 onward, cell shapes progressively accumulated in the six-face (cuboid) shape category (Figure 2E). The systematic unit increase in the number of faces at each generation between G0 and G4 was no longer observed after G4. Hence, the transition between generations 4 and 5 (16C-32C) corresponded to a rupture in the dynamics of embryonic cell shapes.

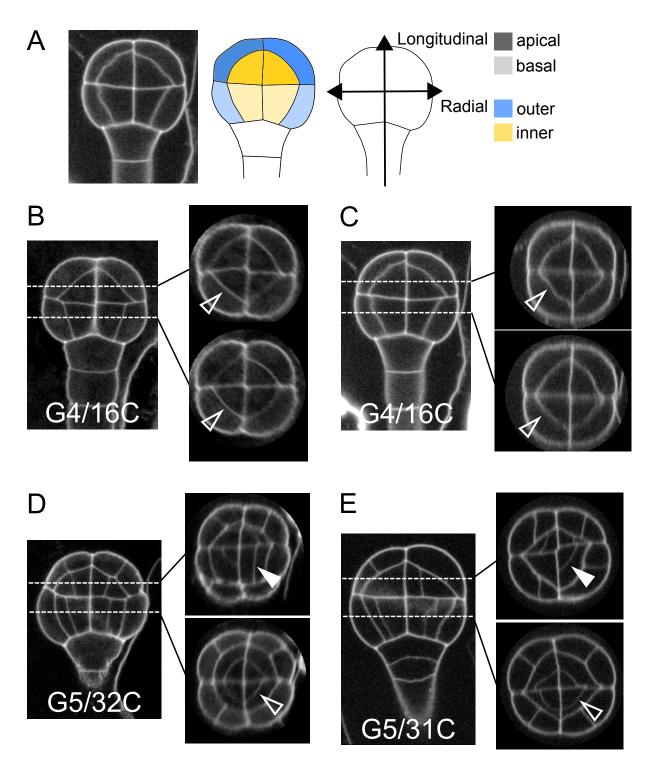

Figure 1: Variability within and between embryos in cell shapes and cell arrangements. (A) The four embryo domains defined by longitudinal and radial axes at stage 16C (longitudinal view): apical/basal \times outer/inner. (BC) Invariant patterns in embryos up to generation 4 (16C). (DE) Starting from generation 5, embryos show variable cell shapes and cell patterns in the apical domains, both between individuals and between quarters in a given individual. Patterns in the basal domains show little or no variability. Some of the new interfaces at G4 (BC) and at G5 (DE) are labeled using arrow heads (*Empty*: invariant patterns; *Filled*: variable patterns).

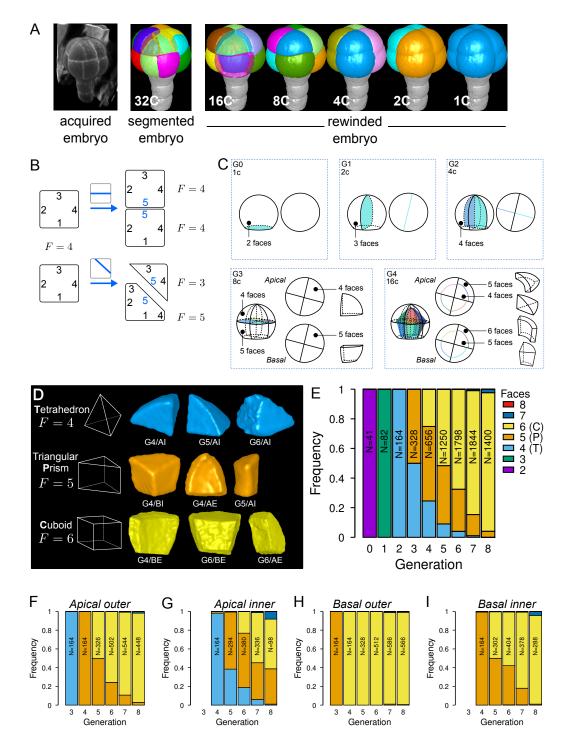

Figure 2: Cell shape diversity in *Arabidopsis thaliana* early embryogenesis. (A) Summary of 3D image analysis pipeline: 3D cell segmentation of confocal image stacks and cell lineage reconstruction by recursive merging of daughter cells. At 32C and 16C stages, some cells are shown transparent to visualize inner cells. (B) Classification of cell shapes based on the number of division interfaces. The scheme illustrates how the number of faces F may change during a division. In both examples, a cell with initially four faces divides. The number of faces in daughter cells depends on the positioning of the new interface and of whether all original faces are represented in the daughter cells. (C) Shape classification during the first four generations. (D) Samples of the three main classes of cell shapes observed during the late four generations. (E) Proportions of shape classes over the whole embryo during the first eight generations. *C*: Cuboid; *P*: Prism; *T*: Tetrahedron. (F-I) Same as (E) over the outer apical (F), the inner apical (G), the outer basal (H), and the inner basal (I) domain. N: number of observed and reconstructed cells.

The evolution of cell shapes at the whole embryo scale masked large differences among the 143 four domains. Indeed, the domain-specific analysis of cell shapes showed that from generation 144 4 onward there was almost no variability in the basal outer domain, where all cells remained in 145 the six-face shape category (Figure 2H). The inner apical domain exhibited the largest variabil-146 ity in cell shape, with cells having four, five and six-faces observed through several consecutive 147 generations (Figure 2G). In the basal inner and in the apical outer domains, the diversity was 148 intermediate, with most cells distributed between the two categories of five and six-face shapes 149 (Figure 2F and I). The dynamics were also similar in these two domains, with a continuously 150 increasing proportion of six-face cells. 151

Overall, these results quantitatively confirmed the visual observations that cell patterns in the apical domain were more variable than in the basal domain. However, our analysis revealed at the same time a limited range of diversity in cell shapes, with most cell shapes falling within one out of three main categories. In addition, our data showed that the dynamics of shape changes during generations 5 to 8 differed from the dynamics observed during generations 1 to 4.

2.2 Diversity in division patterns is domain-specific

Since cell shapes are determined by the positioning of division planes, we asked whether the 159 diversity of cell shapes in the different domains could be related to domain-specific variability in 160 the positioning and orientation of division planes. We examined this hypothesis by enumerating 161 observed cell division patterns in each of the four embryo domains. Cell division patterns were 162 characterized based on the shapes of the mother and of the daughter cells. In addition, we also 163 took into account the relative orientation of the division planes within the embryo. For example, 164 a triangular prismatic cell in the outer apical domain can divide according to three orientations 165 into another prism and a cuboid (Figure 3A). These three possibilities were considered as 166 distinct division patterns. Using lineage trees, we analyzed and guantified the frequencies of 167 division patterns during the last four generations, using both observed patterns and patterns 168 reconstructed at intermediate generations back to the 16C stage. Note that the absence of 169 embryo bending at these stages ensured that the plane orientation in the embryo at the time 170 of division could be correctly inferred even for patterns reconstructed from later stages. 171

Starting from the stereotyped cell patterns of 16C embryos, we found three major orientations of cell divisions in the outer apical domain at the G4-G5 transition (Figure 3B and Figure S3). Divisions in this domain were systematically anticlinal and oriented parallel to an existing cell edge, thus separating one vertex from the two other ones at the outer triangular surface of the cell. The transverse orientation (parallel to the boundary between the apical and basal domains) was less frequent than the two longitudinal orientations, suggesting a directional bias in the positioning of the division plane.

In the inner apical domain, we also found three main orientations of division planes, all oriented
along the longitudinal axis of the embryo (Figure 3D and Figure S4). Only two of these orientations were parallel to an original vertical face of the cell. Divisions parallel to the horizontal
face of the cells were extremely rare. As in the outer apical domain, these results suggested a
preferential positioning of division planes along a limited number of directions.

In contrast with the apical domains, there was only one major orientation of division in each of
 the outer and inner basal domains (Figure 3CE). External cells systematically divided accord-

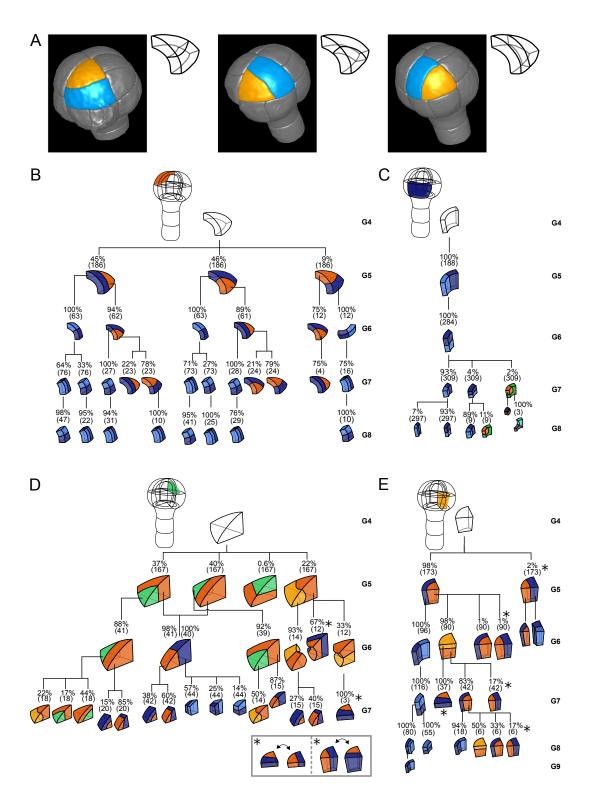

Figure 3: Reconstructed cell lineages in the four embryo domains. (A) Classification of cell division patterns (illustration in the apical outer domain) based on mother and daughter cell shapes and on the absolute orientation of division planes within the embryo. (BCDE) Lineage trees in the apical outer (B), basal outer (C), apical inner (D) and basal inner (E) domains. Each tree shows the observed combinations of cell divisions as a function of cell shapes and of generations. Frequencies were computed based on both observed patterns and patterns reconstructed at intermediate generations when rewinding lineages back to 16C stage from observed configurations. Numbers in parentheses are the total numbers of cases over which the percentages were calculated. Exceptionally rare division patterns are omitted in (B) and (D) for the sake of clarity; complete versions are given in Figure S3 and Figure S4. Asterisks correspond to symmetrical alternatives that were not distinguished in these trees.

ing to a longitudinal anticlinal division (intersecting their external face), with a division plane
 parallel to the lateral faces of the cell. Internal cells also divided longitudinally but along a
 periclinal division (parallel to their external face). This suggests even stronger constraints on
 the positioning of division planes within the basal domain compared with the apical domain.

The contrast between the apical and the basal domains remained during subsequent generations, with strongly stereotyped division orientations in the basal domain, except for the division of the lower cells in the innermost domain at G6 (Figure 3). These results show that variability in the orientation of division planes was larger in the apical than in the basal domain during the latest four generations. By comparison with the stereotyped division patterns up to stage 16C, our analysis further corroborated that the transition between generations 4 and 5 corresponds to a rupture in the dynamics of division patterns.

¹⁹⁷ 2.3 Division patterns correlate with cell shape topology

Since beyond stage 16C the embryo domains differ in the variability of both cell shapes and division patterns, we hypothesized that this variability could reflect shape-specific division patterns. We addressed this issue by exploiting reconstructed lineage trees to analyze division patterns in the three main cell shape categories that we identified.

Cuboid cells were found in all domains at several generations (Figure 3B–E). These cells almost exclusively divided into two cuboid daughter cells. Cuboid division resulting in a triangular prismatic daughter cell was only rarely observed. Hence, division of cuboid cells showed a strong auto-similarity, in that the mother cell shape was almost systematically preserved through the division. Another remarkable feature of the division of cuboids was spatio-temporal stationarity, since the division pattern of these cells was the same at all generations and in all four domains.

Cells with a triangular prism topology were also present in the four domains, when rare division 209 patterns were also considered (Figure 3B-E). These cells showed two division patterns. The 210 first pattern produced two triangular prisms as daughter cells, through a division parallel to the 211 triangular faces. The second pattern yielded one triangular prism and one cuboid, through a 212 division parallel to the quadrilateral faces. Hence, as for cuboid cells, cells with a triangular 213 prism topology showed auto-similarity in their divisions patterns, even though they could also 214 generate new cell shapes. In addition, they also showed spatio-temporal stationarity since 215 their division patterns were similarly observed in all domains and generations where these 216 cells were present. 217

Cells with a tetrahedral topology were only found in the inner apical domain (Figure 3D). They also exhibited two division patterns, one producing two triangular prisms and the other producing one triangular prism and one tetrahedron. Hence, auto-similarity in tetrahedral cells was not systematic. However, their division patterns were similar throughout successive generations, showing they were also exhibiting stationarity.

Together, these results show that each cell shape exhibited specific division patterns that were shared among different generations and among different locations within the embryo. The cuboid shape could be reached from any other cell shape according to the *tetrahedron* \rightarrow *triangular prism* \rightarrow *cuboid* \rightarrow *cuboid* sequence. Hence, the cuboid shape represented an absorbing state. In contrast, the tetrahedral shape was the less stable state. These results explain the decreasing relative frequencies of the tetrahedral and triangular prism cell shapes

through generations of cell divisions observed in the four domains (Figure 2E). Because of 229 shape differences at stage 16C between the four domains, these results may also explain 230 differences in variability of division patterns. For example, the large variability observed in the 231 inner apical domain can be interpreted in light of the intermediate triangular prismatic shape 232 between the tetrahedral and cuboid shapes. Inversely, the absence of shape variability in the 233 outer basal domain can be related to the absorbing state cuboid shape already present at 234 G4 in this domain. However, shapes with identical topology were observed in domains with 235 different variability levels in division orientations, as for example in the outer apical domain and 236 in the inner basal domain that both have triangular prismatic cells at G4. Hence, other factors 237 than cell shape topology alone are probably involved in the variability of cell division patterns. 238

239 2.4 Graph theory of cell division reveals variability is constrained

To assess whether additional factors govern division patterns beyond cell shape topology, 240 we asked whether observed division patterns matched predictions from topologically random 241 divisions. To this end, we used graph theory to describe divisions of polyhedral cells. The 242 polyhedras (tetrahedron, triangular prism, cuboid) corresponding to the three main cell shapes 243 observed during generations 5 to 8 can all be represented as planar graphs and displayed 244 using 2D Schlegel diagrams (Figure 4A) (Grünbaum, 2003). We represented cell divisions as 245 graph cuts on these polyhedral graphs. A graph cut consists in removing some edges in a 246 graph so as to partition the original vertices in two disjoint subsets (Greig et al., 1989). Hence, 247 by removing some edges in the mother cell graph, any cell division resulted in the partitioning 248 of the V vertices of the mother cell into two subsets of p and V - p vertices. The graphs of the 249 two daughter cells were obtained by adding new vertices at edge cuts and by introducing new 250 edges between the added vertices (Figure 4B; Supplementary Information). 251

We used this approach to determine the combinatorial possibilities of division in each of the 252 three shape topologies. For a given mother cell with V vertices, we found that any division 253 separating p vertices (with $p \leq V/2$) from the V - p other ones could be fully described based 254 on p and the number of mother cell edges that were inherited by the daughter cell inheriting 255 the p vertices (Supplementary Information). We further found that in case the inherited edges 256 formed a cyclic graph, the number of faces in one of the two daughter cells was the same as 257 in the mother cell and was at most this number in the other daughter cell. In the case of an 258 acyclic graph, however, at least one daughter would necessarily gain one additional face as 259 compared with the mother cell (Supplementary Information). This theoretical result explains in 260 particular why the number of faces in at least one daughter cell necessarily increases when 261 a tetrahedral cell divides, since the division of tetrahedral cells exclusively corresponds to the 262 acyclic case. This theory shows why tetrahedral cells cannot be an absorbing state and why 263 they represent an inevitable source of cell shape diversity through their divisions. 264

For each cell shape topology, we determined all possible combinations of graph cuts under complete randomness. This allowed us to compute the expected proportions of daughter cells falling within each cell shape category (Supplementary Information). The theoretical distributions we obtained were significantly different from the observed distributions (Figure 4C), thus showing observed division patterns were not compatible with the hypothesis of randomly selected positioning of division planes.

Overall, the predictions made using graph theory under unconstrained, random divisions strongly contrast with observed division patterns, where no or only marginal increases in the number

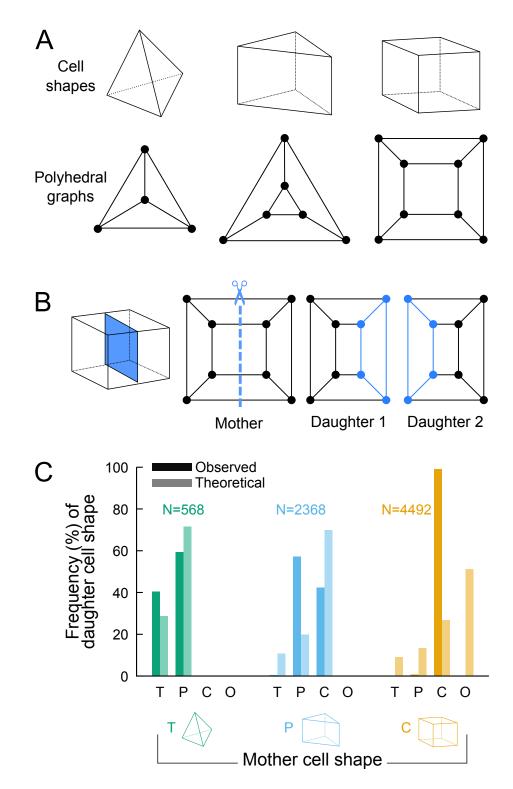

Figure 4: Analyzing cell divisions as graph cuts on polyhedral graphs. (A) The three main cell shapes and their corresponding polyhedral graphs shown as Schlegel diagrams. (B) Cell division as graph cuts: illustration with the division of a cuboid shape. The division shown on the left corresponds to the removal of four edges in the mother cell graph (edges intersected by the dotted line). New vertices and edges added in the graphs of the two resulting daughter cells are shown in blue. (C) Observed and theoretical frequencies of daughter cell shapes during the division of each cell shape. Theoretical predictions were obtained under random graph cuts. *T*: tetrahedron; *P*: triangular prism; *C*: cuboid; *O*: others.

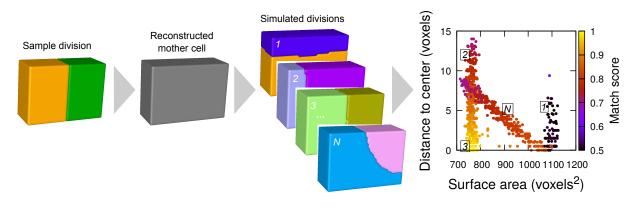

Figure 5: Computational strategy to analyze cell divisions: illustration with a synthetic example (symmetrical vertical division of a cuboid). Starting from a sample division, the mother cell is reconstructed and a large number of divisions at various volume-ratios is simulated. The distance from the cell center and the surface area of the simulated planes are computed. A match score, quantifying the correspondence with the sample division, is computed for each simulated division and represented in pseudo-color. In the present case, the graph shows several families of simulated planes. The location at the bottom left of the distribution of the simulations closest to the sample pattern shows that this division corresponds the minimum plane area among the solutions that pass through the cell center.

of faces was observed during the last four generations. Our analysis thus shows that the observed division patterns are constrained within a limited range of possible combinations.

275 2.5 Division planes obey cell geometry constraints

To understand the origin of the limited variability in cell division patterns, we asked whether 276 cell geometry could be sufficient to account for the observed division planes. We previously 277 showed that, during the first four generations, diverse division patterns (symmetrical as well 278 as asymmetrical, anticlinal as well as periclinal) could be predicted by a single geometrical 279 rule according to which planes obey area minimization conditioned on the passing through the 280 cell center (Moukhtar et al., 2019). The small distance between division plane and cell center 281 observed during the late four generations (Figure S5) suggested that this rule could also hold 282 beyond the first four generations. To examine whether this was indeed the case in spite of 283 diverse division orientations (Figure 3) and volume-ratios (Figure S6), we compared observed 284 division patterns at G5 to predictions derived from a computational model of cell divisions. We 285 used a stochastic model that generated binary partitions of a mother cell at arbitrary volume-286 ratios, under the constraint of minimizing the interface area between the two daughter cells 287 (Moukhtar et al., 2019) (see Material and Methods). Several independent simulations with 288 different volume-ratios were run for each reconstructed mother cell to sample the local minima 289 of interface area in the space of possible binary partitions. 290

Running the model in synthetic shapes showed that repeating independent simulations at various volume-ratios generally produced several families of solutions (Figure 5). Each family corresponded to one of the possible combinations of graph-cuts in the polyhedral graph of the mother cell. The families could be visualized by plotting the distribution of simulation results based on surface area and distance to the cell center. For instance, simulations within a cuboid generated families corresponding to divisions parallel to two of the cuboid faces. In the

distribution plots, such families appeared as vertically oriented clusters because of the similar areas but varying distance to the cuboid center (Figure 5). Other families corresponded to oblique divisions, isolating one vertex or one edge (Figure 5). These families appeared as diagonally oriented clusters because area of these solutions increased when the distance to the center decreased.

We scored the similarity between simulation results and observed patterns based on a match-302 ing index. This index quantified how well a simulated pattern was reproducing the observed 303 one based on the overlap between daughter cells in the two patterns (Figure S7 and Material 304 and Methods). This index ranged between 0.5 (minimal correspondence between simulation 305 and observation) and 1.0 (perfect correspondence). For a sample division obeying the law of 306 area minimization constrained by the passing through the cell center, the simulated divisions 307 that match best the observed pattern should be located at the bottom left of the distribution 308 plot (Figure 5). 309

We first examined divisions in cells of the outer basal domain, which obey a stereotyped 310 symmetrical, anticlinal, and longitudinal positioning of the division planes (Figure 3C and Fig-311 ure S6). The distribution plots of simulated division planes based on surface area and on 312 distance to the cell center were reminiscent of those observed in synthetic cuboid shapes 313 (Figure 6A and Figure S8; compare with Figure 5). Different clusters of simulated planes were 314 observed, revealing the existence of several local minima of the interface area within the space 315 of possible partitionings in these cells (Figure 6A). In all analyzed cells, the simulated planes 316 that matched the observed patterns were systematically found at the bottom left of the distri-317 bution plot (Figure 6A and Figure S8), showing that these matching planes were minimizing 318 the surface area among the solutions that pass close to the cell center. Two other clusters 319 of simulated planes, corresponding to either obligue or horizontal divisions, poorly matched 320 observed patterns and had a larger interface area and/or a larger distance to the centroid. 321 Hence, the anticlinal, highly symmetrical division of the basal outer cells at stage 16C of the 322 embryo was perfectly predicted by the division rule. In most cells, the matching solutions were 323 at the bottom of a cluster of solutions displaying a wide range of distances to cell center but 324 comparable areas, corresponding to a family of parallel longitudinal divisions. This confirmed 325 our previous result that, by the combined minimization of distance to cell center and of inter-326 face area, the rule can predict both the positioning of the division plane and the volume-ratio 327 of the division (Moukhtar et al., 2019). 328

In the external apical domain, where slightly asymmetrical, non stereotyped divisions were 329 observed (Figure 3B and Figure S6), we ran the model in reconstructed mother cells that 330 divided along the three main modes of division observed in this domain. As in the basal 331 domain, the model generated different families of solutions within each mother cell (Figure 6B-332 D), showing the existence of different local minima of surface area for a given cell geometry. 333 In each case, one of these cluster faithfully matched the observed pattern. The location of this 334 cluster at the bottom left of the distribution plot suggested that for a given mother cell shape, 335 the observed division plane could be predicted based on area minimization conditioned on the 336 passing the through the cell center (Figure 6 and Figure S10, S11 and S12). Remarkably, 337 simulations belonging to the other, non-matching clusters corresponded to division patterns 338 observed in other cells (Figure 6B-D). These data can be interpreted as showing the existence 339 of three principal local minima of surface area in the space of partitionings of each apical 340 external cell, corresponding to the order 3 rotation invariance of triangular prisms. Our results 341 also show that cells divide according to the area minimum that fits best with the same division 342 rule that operates in the outer basal domain. 343

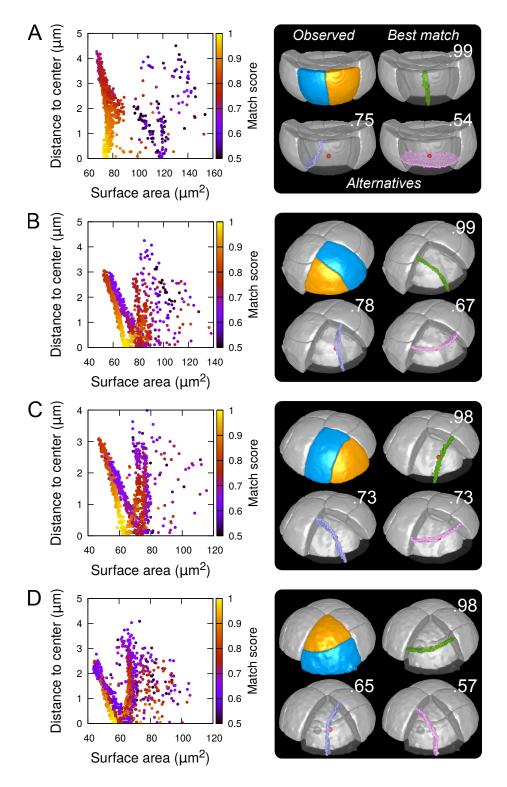

Figure 6: Modeling division patterns at G5 in external cells based on geometrical features. (A) *Left*: distribution plot of simulation results in a basal outer cell (N=1000). Simulated planes are positioned based on their surface area and distance to the mother cell center. The color code indicates the match score between simulated and observed planes. *Right*: observed daughter cells (*Blue* and *Orange*); three simulated planes are shown in the reconstructed mother cell (*Transparent*). *Green*: simulation matching best with observed pattern. *Lavender* and *Pink*: simulations with alternative orientations. Numbers show the corresponding match scores. *Red dot*: mother cell center. (BCD) Same as (A) for three apical outer cells that divided along the three main orientations of division.

As in the outer basal domain, simulation results within basal inner cells (were observed divi-344 sions were stereotyped, periclinal and strongly asymmetrical; Figure 3E and Figure S6) were 345 distributed among different patterns. However, a key difference with the external domain was 346 that a few, if any, simulations reproduced the observed divisions (Figure 7A and Figure S9). 347 Since the probability of generating a given interface with the model is inversely related to its 348 area, the absence or scarcity of reproduced observed patterns suggested that the periclinal 349 divisions in the inner basal domain did not correspond to the global minimization of interface 350 area. This was confirmed by the fact that the rare simulations reproducing observed divisions 351 had generally larger interface areas than alternatives passing as close to the cell center. 352

In the internal apical cells, where experimental variability was the largest (Figure 3D and Fig-353 ure S6), we found different results depending on the orientation of the division. For cells where 354 division occurred parallel to an existing interface (yielding a triangular prism and a tetrahe-355 dron as daughter cell shapes), we obtained results comparable to those obtained in external 356 apical cells. Several clusters of simulations were obtained within each cell, and the one re-357 producing the actual division was in most cases located at the bottom left of the distribution 358 (Figure 7B; Figures S13 and S14). In the other clusters, we observed simulated divisions that 359 corresponded to patterns observed in other cells (Figure 7B). Hence, divisions in these cells 360 were consistent with the existence of multiple local minima of interface area and with the se-361 lection, among these, of the minimum that also fits with the minimization of distance to the cell 362 center. In cells dividing radially (yielding two triangular prisms for daughter cell shapes), some 363 cells complied with this rule (Figure 7C; Figure S15) but we also found as many that did not. 364 In the latter cells, several clusters corresponding to various division orientations were again 365 observed. However, the cluster reproducing the observed division was either overlapping with 366 other clusters or was located farther away from the heel of the distribution plot compared with 367 the alternative clusters (Figure 7D). This showed that in these cells, the observed division 368 was not unequivocally corresponding to the minimization of distance to the cell center and of 369 interface area. 370

2.6 Validation of model predictions

Simulation results obtained with our model suggested that asymmetries in mother cell geome-372 try could bias the positioning of the division plane. We evaluated this prediction by examining 373 the correlation between asymmetries in the mother cell geometry and the division plane ori-374 entation. We performed this analysis on the divisions of the 16C apical cells. For these cells, 375 there was indeed, at the same time, strong self-similarity by rotation of the corresponding 376 idealized shapes (tetrahedron in the inner part, triangular prism in the outer one) and large 377 variability in the orientation of the division planes. For each reconstructed mother cell, we 378 quantified its radial asymmetry by the ratio of left to right extensions and we quantified its rela-379 tive longitudinal extension by the ratio of its height to its maximal radial extension (Figure 8A). 380

For internal apical cells dividing longitudinally with a triangular prismatic daughter cell on the left, the left extension was on average smaller than the right extension (Figure 8B, *Green*). The reverse was observed for the internal cells that divided with a triangular prismatic daughter located on the right (Figure 8B, *Yellow*). For the internal cells that divided horizontally or longitudinally with no left/right asymmetry in plane positioning, there was no pronounced radial asymmetry (Figure 8B, *White* and *Pink*) but, compared with cells that divided longitudinally, they exhibited a larger longitudinal extension (Figure 8C). Hence, in internal apical cells, the

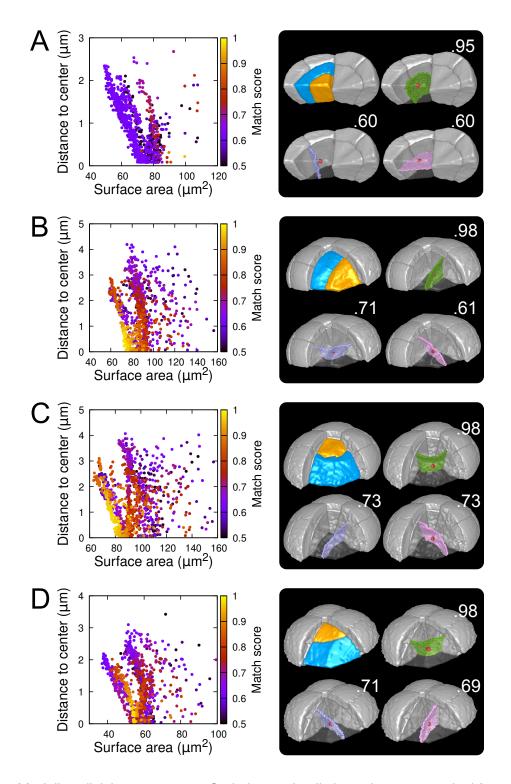

Figure 7: Modeling division patterns at G5 in internal cells based on geometrical features. (A) *Left*: distribution plot of simulation results in a basal inner cell (N=1000). Simulated planes are positioned based on their surface area and distance to the mother cell center. The color code indicates the match score between simulated and observed planes. *Right*: observed daughter cells (*Blue* and *Orange*); three simulated planes are shown in the reconstructed mother cell (*Transparent*). *Green*: simulation matching best with observed pattern. *Lavender* and *Pink*: simulations with alternative orientations. Numbers show the corresponding match scores. *Red dot*: mother cell center. (BCD) Same as (A) for three apical inner cells.

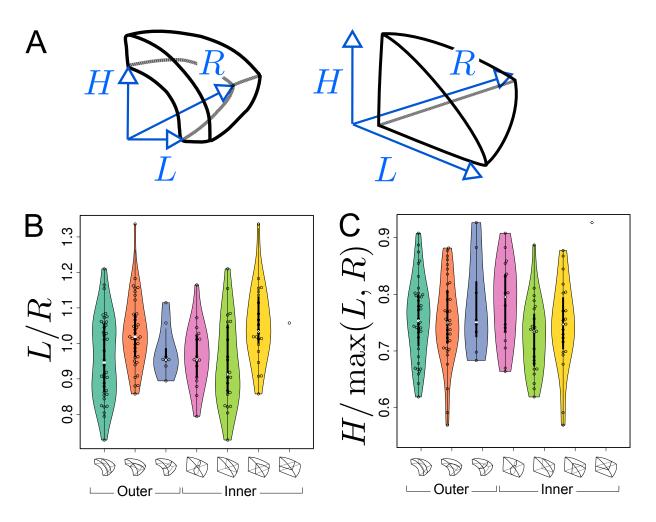

Figure 8: Asymmetries in mother cell geometry in the apical domain at stage 16C and their relations with division plane orientation. (A) Measured extensions of outer (*Left*) and inner (*Right*) mother cells. (B) Radial asymmetry. (C) Relative longitudinal extension. Measurements were performed on mother cells reconstructed at G4/16C from observed embryos at G5 or G6.

position of the division plane matched the geometrical asymmetry of the mother cell along
 different directions.

Similar trends were observed in the outer apical cells. Among these, cells dividing longitudi-390 nally with a cuboid daughter cell located on the left had on average a smaller left than right 391 extension (Figure 8B, Turquoise). The reverse was observed for the cells that divided with a 392 cuboid daughter cell located on the right (Figure 8, Orange). As in the inner domain, the radial 393 asymmetry was less pronounced for the outer apical cells that divided horizontally (Figure 8B, 394 Blue). Compared with the inner domain, however, it was less clear whether their longitudinal 395 extension was larger than in cells dividing longitudinally (Figure 8C), which may be due to the 396 limited number of cells that were observed to divide horizontally. 397

Overall, these results show that apical cells at 16C presented directional asymmetries and that division planes tended to be oriented parallel to the smallest extension. This suggests that the diversity of division plane orientations for a given shape topology reflects geometrical diversity, in accordance with the predictions from our geometrical division rule.

2.7 Attractor patterns buffer variability of cell division orientation

The above results show that from one generation to the next, there is large variability in cell division orientation in some embryo domains. Across several generations, the combinatorial possibilities between different orientations can potentially lead to a large number of distinct cell patterns. To determine whether this was indeed the case, we analyzed division patterns over two consecutive generations.

In the outer apical domain, three main orientations of cell divisions were observed at G5. Variability in division orientation was less pronounced in the subsequent generations, which presented alternation of division plane orientations (Figure 3B). As a result, similar cell patterns could be reached at generation 6 through different sequences of division events from G4 (Figure 9A).

In the protodermal layer of the basal domain, some variability was first observed at the transi-413 tion between G6 and G7, where in 16 out of 303 cases (5.3%) the division plane was oriented 414 transversely instead of longitudinally (Figure 3C). Similarly, some cells (19/297, 6.4%) at G7 415 divided longitudinally instead of transversely (Figure 3C and Figure 9C). Some cells in early 416 heart stage embryos of our collection had already underwent an additional round of cell di-417 vision, allowing to examine the evolution of such patterns. We observed that the cells that 418 had exceptionally divided longitudinally at G7 led to daughters cells that divided transversely 419 at the next generation, thus restoring at G9 the same 2×2 checkerboard cell pattern than ob-420 tained along the transverse then longitudinal path followed in most embryos from G7 to G9 421 (Figure 9C). 422

In the inner basal domain, cell divisions were strongly stereotyped, following periclinal patterns 423 that yield the precursors of the future vascular tissues (Figure 3E and Figure 9B, Left). At G5, 424 however, 3 out of 153 cases (2%) in our dataset showed an anticlinal pattern (Figure 3E and 425 Figure 9B, Right). One of these cases was reconstructed from an embryo acquired at G6. 426 This allowed to observe that one of the two daughter cells of the anticlinal division at G5 had 427 divided periclinally at G6, thus restoring the formation of a new cell layer as in the standard 428 case (Figure 9B). This suggests that, in the inner basal domain also, similar cell patterns can 429 be reached through different paths in spite of variability in division plane positioning. 430

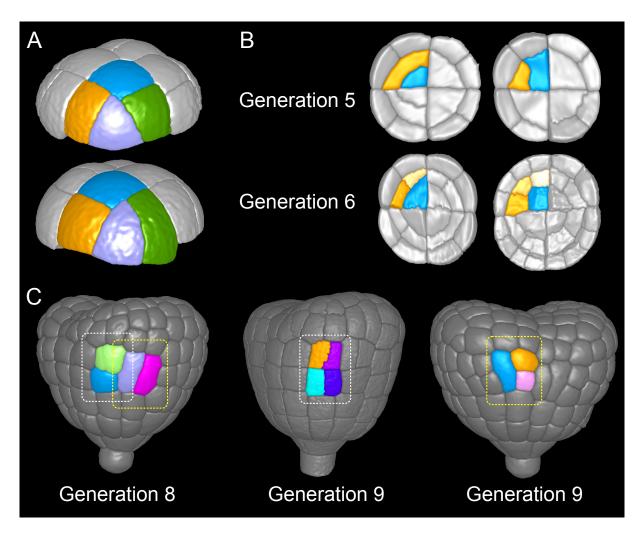

Figure 9: Attractor patterns buffer variability in division plane positioning. (A) Similar cell patterns observed at G6 in the apical outer domain that have been reached through distinct cell division paths from G4. (B) Main (*Left*) and rare (*Right*) division patterns in the inner basal domain at G5 and corresponding patterns at G6. (C) Main (*White box*) and rare (*Yellow*) patterns observed at G8 and G9 in the outer basal domain.

These results show the existence of invariant cell patterns that can be reached through different paths of successive cell divisions from stage 16C. This suggests that a significant part of the variability in cell division positioning observed during the late four generations of embryogenesis is buffered when considering time scales that span several generations, thus ensuring the construction of robust cell organizations in spite of local spatio-temporal variability.

436 **3** Discussion

Previous attempts to decipher the principles that underlie the position and orientation of di-437 vision planes have been focused on geometrical rules predicting the division plane position 438 relatively to the mother cell geometry, and on their impact on global tissue organization and 439 growth. Much less attention has been given to the prediction of tissue organization with a ge-440 ometrical precision at the individual cell level. The Arabidopsis embryo is a remarkable model 441 to address the existence and nature of geometrical division rules, as it presents invariant di-442 vision patterns during the first four generations followed by intra- and inter-individual variable 443 patterns for the next four generations. Here, we provided a detailed quantitative analysis of 444 this variability and used theoretical and computational modeling of cell divisions to investigate 445 its origin. We show that strong regularities are hidden behind the apparent variability and that 446 most of the observed patterns can be explained by a deterministic division rule applied in a 447 geometrical context affected by the stochasticity of the precise positioning of division plane. 448

Deterministic cell division patterns have been interpreted in light of geometrical rules linking 449 cell shape to division plane (Minc and Piel, 2012). The shortest path rule, according to which 450 cells divide symmetrically so as to minimize the interface area between daughter cells (Errera, 451 1888), has been shown to operate in several plant tissues such as fern protonema (Cooke 452 and Paolillo Jr, 1980), algae thallus (Dupuy et al., 2010), Arabidopsis meristem (Sahlin and 453 Jönsson, 2010) or early embryo (Yoshida et al., 2014; Moukhtar et al., 2019). However, it was 454 also shown that stochastic rules are required to account for division patterns in many tissues 455 with 2D geometries (Besson and Dumais, 2011). Hence, a stochastic division principle would 456 a priori be the most likely candidate interpretation of the variable division patterns we reported 457 here in late Arabidopsis embryo. Our results actually point to a different interpretation for 458 this variability. Indeed, for a given cell geometry, the observed plane orientation and position 459 matched in most cases the global optimum according to the rule of area minimization condi-460 tioned on the passing through the cell center, and we could correlate the plane orientation with 461 asymmetries in directional cell extensions. 462

Based on these results, we propose that variability in cell division patterns could originate from 463 fluctuations in mother cell geometry rather than from the division rule. The tetrahedral and 464 triangular prismatic shape topologies of apical cells at stage 16C are rotationally symmetric. If 465 cells were perfectly symmetric, the various plane orientations (4 in inner apical cell, 3 in outer 466 apical cells) would be equally probable according to the geometrical rule. We hypothesize that 467 actual geometrical deviations from perfect symmetry suppress this equi-probability and induce 468 a single global minimum, which would be selected during the division. Accordingly, variability 469 in division plane orientations in the apical domain would not ensue from a stochastic division 470 rule, but rather from a deterministic principle expressed within a varying mother cell geometry. 471 Note, however, that our sample sizes do not allow to definitively rule out a possible stochastic 472 selection of division plane orientation, in particular in light of the results obtained in the inner 473

apical domain with cells dividing longitudinally. Further studies will be required to definitively
 distinguish between these two hypotheses and to further dissect the respective contributions
 of intrinsic (variability of plane positioning for a given cell geometry) and of extrinsic (variability

⁴⁷⁷ due to fluctuations in mother cell geometry) noise in the selection of the division plane.

Our data reveal an abrupt change in the dynamics of cell shapes and cell division patterns at 478 the transition between generations 4 (16C) and 5 (32C). Up to generation 4, division patterns 479 were stereotyped and each generation corresponded to the introduction of a new cell shape 480 with a unit increase in the number of cell faces. In contrast, we observed from generation 481 5 onward a strong variability in division patterns with a concomitant reduction in cell shape 482 variability, as cell shapes progressively converged towards a single 6-face shape topology. 483 Graph cut theory on polyhedral graphs together with our hypothesis of a deterministic division 484 principle operating in a stochastic cell geometry offer a parsimonious interpretation of this 485 apparent paradox. On the one hand, our theory shows that the division of the tetrahedral 486 cells from generation 2 inevitably generates novelty with one obligatory prismatic daughter 487 cell shape. We also show that triangular prismatic shapes that appear at generation 3 are 488 theoretically twice less self-reproducible than the cuboid shapes that appear for the first time 489 at generation 4. Beyond this stage, cell division through the cell center and area minimization 490 tend to preserve the cuboid shape of the mother cell in the two resulting daughters. On the 491 other hand, variability in division patterns emerges at generation 5 because of the almost, 492 but not exactly, rotation-symmetrical cell geometries reached for the first time at stage 16C. 493 Hence, our study reveals that a common underlying geometrical rule can account for cell 494 division patterns with radically different traits. 495

Our interpretation of the variability in division orientations raises the issue of the origin of vari-496 ability in cell geometry within a given cell shape category. In spite of genetic controls, any 497 given division pattern is subject to random fluctuations that affect the precise positioning of the 498 cleavage planes (Schaefer et al., 2017). This noise in the positioning of division planes ac-499 cumulate through embryo generations, resulting in non-perfectly symmetrical shapes at stage 500 16C. A modeling study previously reported the importance of stochastic positioning of cleavage 501 planes at the 2C-4C transition in the patterning of vascular tissues (De Rybel et al., 2014). In 502 our case, it is likely that errors accumulated over the 2C-4C and 4C-8C transitions contribute to 503 the geometrical asymmetries that bias division plane positioning at the 16C-32C stage. Hence, 504 our results strongly suggest that not only genetic patterning (De Rybel et al., 2014) but also 505 division patterning could be influenced by the geometric memory of past stochastic events. 506

Several studies have highlighted the importance of noise and stochastic processes in plant 507 developmental programs (Korn, 1969; Meyer and Roeder, 2014; Hong et al., 2018). At the 508 cellular level, these processes have been described essentially for cell growth. For example, 509 heterogeneity in cell growth patterns was shown essential for the robustness of organ shapes 510 (Hong et al., 2016). It is yet unclear, however, whether variability in division orientation has 511 functional implications, be it in the mechanical shaping of the embryo or in the establishment 512 of growth gradients that would subtend the future evolution of the embryonic shape. Impor-513 tantly, homeostatic mechanisms compensating for cell growth variability have been described. 514 For example, at the cellular level, larger relative growth rates in smaller cells (Willis et al., 2016) 515 or DNA-dependent dosage of a cell cycle inhibitor (D'Ario et al., 2021) have been proposed 516 to subtend cell size homeostasis in the shoot apical meristem; at the tissue level, mechanical 517 feedbacks have been described that buffer growth heterogeneities between cells (Hervieux 518 et al., 2017). We reveal here in several embryo domains the existence of attractors in embryo 519 cell patterns that can be reached through different division sequences, thus generalizing past 520

⁵²¹ observations in the root embryonic axis (Scheres et al., 1995). As for cell growth patterns, ⁵²² these attractor patterns can be interpreted as buffering heterogeneity in division plane orien-⁵²³ tation. Hence, our results reveal a new compensation mechanism at the cellular level that, in ⁵²⁴ addition to known cell growth regulations, could operate in developing plant tissues to generate ⁵²⁵ robust supra-cellular patterns.

Previous studies have modeled the topology of divisions in 2D. It was shown for example 526 how an average of 6 neighbors per cell could emerge from random symmetrical divisions 527 (Graustein, 1931; Gibson et al., 2006). Based on Markov chain modeling, it was also shown 528 how steady-state distributions in the number of faces or of neighbors could be computed in pro-529 liferating epithelia (Gibson et al., 2006; Cowan and Morris, 1988). The topology of a 2D division 530 in a polygonal shape can simply be modeled as a combinatorial choice of two polygonal edges 531 (Cowan and Morris, 1988; Gibson et al., 2006). Unfortunately, this approach cannot be gener-532 alized to polyhedral cells in three dimensions. Here, we proposed a solution to this problem by 533 modeling the topology of division in polyhedral cells as cuts on polyhedral graphs. The large 534 differences between predicted daughter shape distributions under topologically random divi-535 sions of mother cells and observed distributions revealed the existence of strong constraints 536 on division plane positioning at the 16C-32C transition. Though this is probably challenging, 537 it would be of further interest to explore the potential of the proposed graph theoretical ap-538 proach to address the existence of, and to theoretically derive, the asymptotic distributions 539 of 3D shapes under random or more elaborate topological rules, as was done in 2D tissues 540 (Cowan and Morris, 1988; Gibson et al., 2006). 541

The results of the present study show that the same geometrical rule that accounted for cell 542 division patterns during the first four generations is also consistent with the positioning of di-543 vision planes beyond the dermatogen stage. However, we found contrasting results among 544 different embryo domains and, to a lesser extent, among different orientations of division. In 545 the protodermal domains of both the upper and the lower domains, both the volume-ratios and 546 the positioning of the cleavage interface could be accurately predicted following the geomet-547 rical rule. In contrast, divisions markedly departed from the rule in the lower inner domain. 548 An intermediate situation was observed in the inner apical domain, where the rule accounted 549 for all but the longitudinal radial orientation. Auxin signaling has been suggested as required 550 for cells to escape the default regime of division plane minimization and to control periclinal 551 divisions at the previous (8C-16C) generation of cell divisions (Yoshida et al., 2014), which 552 could involve a modulation of cell geometry by auxin signaling (Vaddepalli et al., 2021). At 553 subsequent generations, it has instead been reported that the first vascular and ground tissue 554 cells divided periclinally along their maximal (longitudinal) extension when the auxin response 555 was impaired by a ARF5/MP mutation or local ARF inhibition (Möller et al., 2017). In the shoot 556 apical meristem, cells preferentially divide longitudinally at the boundaries of emerging organs, 557 where auxin responses are low (Louveaux et al., 2016). Hence, it is unclear whether specific 558 auxin responses are involved in the longitudinal divisions observed in the inner domains. Me-559 chanical forces have been shown to alter division plane orientations in in vitro-grown cells 560 (Lintilhac and Vesecky, 1984), and it was shown in the shoot apical meristem that tissue me-561 chanical stress could override cell geometry in the specification of plane positioning (Louveaux 562 et al., 2016). It was also recently found that the orientation of cell division during lateral root 563 initiation correlated with cellular growth (Schütz et al., 2021). Hence, one can speculate that 564 the differences in cell environments between the inner and the outer embryo domains may in-565 duce different mechanical contexts with differential impacts on the determination of the division 566 plane orientation. 567

4 Material and methods

4.1 Sample preparation and image acquisition

mPS-PI staining. Arabidopsis siliques were opened and fixed in 50% methanol and 10% acetic 570 acid five days at 4°C. Samples were rehydrated (ethanol 50%, 30%, 10% and water) then 571 transferred 3 hours in a 0.1 N NaOH 1% SDS solution at room temperature. Next, samples 572 were incubated 1 hour in 0.2 mg/ml α -amylase (Sigma A4551) at 37°C and bleached in 1.25% 573 active CI⁻ 30 to 60 seconds. Samples were incubated in 1% periodic acid at room temperature 574 for 30 min and colored by Schiff reagent with propidium iodide (100 mM sodium metabisulphite 575 and 0.15 N HCI; propidium iodide to a final concentration of 100 mg/mL was freshly added) 576 overnight and cleared in a chloral hydrate solution (4 g chloral hydrate, 1 mL glycerol, and 2 577 mL water) few hours. Finally, samples were mounted between slide and cover slip in Hoyer's 578 solution (30 g gum arabic, 200 g chloral hydrate, 20 g glycerol, and 50 mL water) using spacers. 579

⁵⁸⁰ Confocal microscopy and image acquisition. Acquisitions were done with a Zeiss LSM 710 ⁵⁸¹ confocal microscope as described previously (Truernit et al., 2008). Fluorescence signals were ⁵⁸² recorded using a 40x objective and digitized as 8-bit 3D image stacks with a near-to-optimal ⁵⁸³ voxel size of $0.17 \times 0.17 \times 0.35 \ \mu m^3$.

4.2 Image processing and analysis

Noise in acquired 3D images was attenuated by applying Gaussian smoothing (with parameter 585 $\sigma = 0.5$) under the Fiji software (Schindelin et al., 2012). Cells were segmented by applying 586 the 3D watershed transform (Vincent and Soille, 1991) to images after non-significant minima 587 had been removed using minima imposition (Soille, 2003). The two operations were performed 588 using the Morphological Segmentation tool of the MorphoLibJ suite (Legland et al., 2016). All 589 segmentations were visually checked and a modified version of the MorphoLibJ plugin was 590 developed to correct over- and under-segmentation errors, if any, based on the interactive 591 modification of watershed initialization seeds. 592

The cell lineages were manually back tracked, processing embryos from the younger to the older ones (using the number of cells as a proxy for developmental stage). Based on the cellular geometries and organizations, sister cells were paired so as to minimize wall discontinuities in reconstructed mother cells. Lineage reconstruction was performed using TreeJ, an in-house developed Fiji plugin. Reconstructed cell lineage trees were exported as Ascii text files for further quantitative analysis.

Segmented images and lineages trees were processed under Matlab (MATLAB, 2012) to lo-599 calize cells within the embryo and to assign them to embryo domains (inner or outer, apical 600 or basal). Cell volumes were obtained by multiplying the number of voxels of each cell by 601 unit voxel volume (product of spatial calibration in XYZ directions). Mother cells were recon-602 structed by merging the segmentation masks of daughter cells. For each division, volume-ratio 603 was computed as the ratio between the smaller cell volume and the mother cell volume. Three-604 dimensional triangular meshes of segmented cells and of their interfaces with neighbour cells 605 were computed under AvizoFire (©2013 Visualization Sciences Group, an FEI Company). The 606 cell interface meshes were processed by a python script to automatically measure ratios of 607 cell extensions along different directions. To this end, we first computed the intersection lines 608

⁶⁰⁹ between side meshes by determining their shared vertices. Then, vertices at intersections be-⁶¹⁰ tween three connected intersection lines were identified as cell corners. Cell extensions were

obtained as Euclidean distances between corner vertices.

The number of faces per cell was computed using cell lineage trees with a python script. 612 Mother cells were reconstructed up to the first embryonic cell by recursively merging sister 613 cells. During this process, the generation at which each division plane had been formed was 614 recorded. This allowed to determine for each observed cell the number of different genera-615 tions at which interfaces with neighboring cells had been created. This number was taken as 616 the number of faces for the cell. For the first embryonic cell, there were two interfaces, one 617 corresponding to the wall separating this cell from the suspensor and the other corresponding 618 to the separation with the outside of the embryo. 619

4.3 Computer modeling of cell divisions

Computer simulations. Cell divisions in reconstructed mother cells were simulated using the 621 model we introduced previously (Moukhtar et al., 2019). For each simulation, the volume-ratio 622 ρ of the division (volume of the smaller daughter cell to the volume of the mother) was randomly 623 drawn between 0.2 and 0.5. Each voxel of the mother cell mask was initially assigned to one 624 or another of the two daughter cells with probability ρ and $1 - \rho$, respectively. The Metropolis 625 algorithm (Metropolis et al., 1953) was then used to iteratively minimize the interface area 626 between the two daughter cells. The algorithm iterated 5000 cycles of N steps each, N being 627 the number of voxels in the binary mask of the mother cell. At each step, a voxel was randomly 628 chosen. Its assignment to one or the other of the two daughter cells was flipped if this induced a 629 decrease in the interface area. Otherwise, the flip was accepted with probability $\exp(-\beta\Delta A)$, 630 where ΔA represented the change in interface area induced by the flip. The parameter β 631 was automatically adjusted at the end of each cycle so that about 5%, on average, of the 632 candidate flips that would increase interface area were accepted. For each mother cell, 1000 633 independent simulations were run. 634

Scoring simulated divisions. The similarity between the simulated and observed divisions was scored based on their spatial overlap (Figure S7). Let *A* and *B* denote the sets of voxels in the two daughter cells of an observed division, and let A' and B' denote the two sets in a simulated division. The score quantifying the match between the two partitions of the mother cell space was defined as:

$$\operatorname{score} = \max\left\{\frac{|A \cap A'| + |B \cap B'|}{|A \cup B|}, \frac{|A \cap B'| + |B \cap A'|}{|A \cup B|}\right\}$$

⁶³⁵ This score varied between 0.5 (the minimum possible overlap) and 1.0 (perfect overlap).

Acknowledgments

⁷⁶⁵ Supplementary information: predicting the topology of ran ⁷⁶⁶ dom divisions using graph cuts on polyhedral graphs

We consider the main three cell shapes observed during late embryogenesis in *Arabidopsis thaliana*. These shapes are the tetrahedron, triangular prism, and cuboid (containing 4, 5, and 6 faces, 4, 6, and 8 vertices, and 6, 9, and 12 edges, respectively). Our objective here is to enumerate the different ways of dividing these cell shapes and to characterize the resulting daughter shapes. The key to our analysis is to represent cell shapes as planar polyhedral graphs and cell divisions as graph cuts on these polyhedral graphs.

Supplementary Figure S1: Polyhedral graphs for the three main cell shapes found in *Arabidopsis thaliana* early embryogenesis. Note that in these representations (Schlegel diagrams), the outside counts as one face of the corresponding polyhedron.

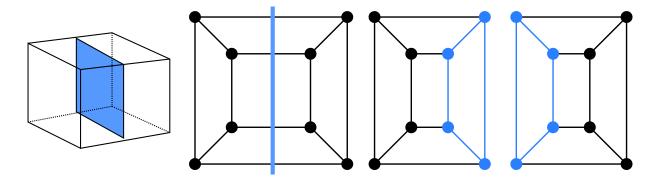

Any convex polyhedral cell shape with F faces can be represented by a 3-connected planar graph G of V vertices inter-connected by E edges (polyhedral graph). Such graphs can be represented in 2D by Schlegel diagrams (Figure S1). Because of the 3-connectivity of the corresponding graph, applying Euler's formula (V - E + F = 2) to any of these shapes gives the following relations:

$$2E = 3V$$
$$2F = 4 + V$$

Hence, we only need to determine the number of vertices of the daughter cells to characterize a cell division in terms of the abstract resulting cell shapes.

Given that cell divisions avoid existing vertices, any division splits the cell vertices in two disjoint 780 sets of vertices. This sets are non-empty because cell division planes extend from one face 781 of the mother cell to another one. Cases where a division plane extends from an existing 782 cell face to the same face are extremely rare and unknown in the embryo. Hence, a cell 783 division corresponds to a graph cut, whereby a number of edges are removed to yield two 784 disconnected subgraphs. Following cut, each subgraph is completed by adding new vertices 785 at the cut positions. A new edge is also introduced for each pair of new vertices located on 786 the same face of the mother cell. The two resulting graphs are the graphs of the two daughter 787 cells (Figure S2). One consequence of representing cell division as a graph cut is that each 788 face of the original mother cell is cut at most once. This implies that we do not consider curved 789 division planes that would fold back to intersect a face more than once. This is consistent with 790 biological observations in the plant embryo. 791

⁷⁹² A division can be characterized by a couple of integers (p, q), where p and q are the number ⁷⁹³ of initial vertices that are separated by the division. Since q = V - p, the division is actually

Supplementary Figure S2: Cell division as cuts on polyhedral graphs: illustration with the division of a cuboid. The division on the left corresponds to the edge cut shown in the middle. Completing the two subgraphs of this cut with nodes and edges (*Blue*) yields the two subgraphs of the daughter cells. The obtained subgraphs correspond to two cuboids, as expected for the considered division.

fully characterized by p only. We call p-division a division that separates p vertices from the

V-p other vertices (p > 0). For example, the 1-divisions are the divisions whereby one of the

vertices is separated from all the other ones ("corner" division). Since the p-divisions and the

 $_{797}$ q-divisions with q = V - p are two identical sets of divisions, we limit ourselves to situations

where
$$p \leq q$$
, i.e., $p \leq V/2$.

We note N(p) the number of possible p-divisions of a given cell shape. For each of these 799 divisions, we note K(p) the number of removed edges (= size of the edge cut-set); $V_p(p)$, 800 $E_p(p)$ and $F_p(p)$ the total number of vertices, edges and faces in the daughter cell that inherits 801 the p vertices; $V_q(p)$, $E_q(p)$ and $F_q(p)$ the total number of vertices, edges and faces in the 802 daughter cell that inherits the remaining q = V - p vertices; $E_p^*(p)$ and $E_q^*(p)$ the number of 803 edges that are inherited from the mother cell by each of these two daughter cells, respectively 804 (= number of edges in the subgraphs of G induced by the p and q vertices, respectively). We 805 derive below the expressions of all these quantities as functions of p. 806

⁸⁰⁷ Each edge cut creates a new vertex for each daughter cell. We thus have, for any *p*:

$$V_p(p) = p + K(p)$$

$$V_q(p) = q + K(p)$$

Since each vertex is connected to three edges, the maximal number of possible cuts is 3p

(remember that $p \le q$). Each edge inherited by a daughter cell from its mother removes two potential cuts (one for each end-vertex). This gives:

$$K(p) = 3p - 2E_p^*(p)$$

= $3q - 2E_a^*(p)$

811 We thus have:

$$V_p(p) = 2 [2p - E_p^*(p)]$$

$$V_q(p) = 2 [2q - E_q^*(p)]$$

812 which we can write

$$V_p(p) = 2 Q_p(p)$$
$$V_q(p) = 2 Q_q(p)$$

813 where

$$Q_p(p) = 2p - E_p^*(p)$$
$$Q_q(p) = 2q - E_q^*(p)$$

This finally leads to the following simple expressions for the number of edges and faces in the daughter cells:

$$E_p(p) = 3 Q_p(p)$$
$$E_q(p) = 3 Q_q(p)$$

 $F_p(p) = 2 + Q_p(p)$ $F_q(p) = 2 + Q_q(p)$

816

$$E = E_p^*(p) + E_q^*(p) + K(p)$$

we also have

$$Q_q(p) = V/2 + p - E_p^*(p)$$

In a graph-theoretical perspective, we can thus fully describe a p-division and the resulting daughter cell shapes by two parameters only: the number p of original vertices and the number

 $E_p^*(p)$ of original edges that are inherited by the "smallest" ($p \le q$) of the two daughter cells.

To go further we must distinguish two situations, depending on whether the subgraph induced by the *p* vertices and their $E_p^*(p)$ edges is cyclic or not.

If the subgraph induced by the p vertices and their $E_p^*(p)$ edges contains no cycle (this is systematically the case for p < 3), then we have:

$$E_n^*(p) = p - 1$$

⁸²² This gives the following features for a division induced by two acyclic subgraphs:

$$Q_p(p) = p+1$$

$$Q_q(p) = V/2 + 1$$

$$V_p(p) = 2(p+1)$$

$$V_q(p) = V + 2$$

$$E_p(p) = 3(p+1)$$

$$E_q(p) = 3V/2 + 3$$

$$F_p(p) = p + 3$$

$$F_q(p) = V/2 + 3$$

⁸²³ One corollary of these results is that:

$$F_p(p) \leq F+1$$

$$F_q(p) = F+1$$

Hence, a division "in the acyclic case" systematically yields a daughter cell with one additional

face compared with the mother. The other daughter cell has at most one additional face.

For the shapes we consider, we have $p \le 4$. In this particular case, the presence of a cycle in the subgraph induced by the p vertices ($p \ge 3$) and their $E_p^*(p)$ edges necessarily leads to:

$$E_p^*(p) = p$$

- which yields the following features for a division induced by a cyclic subgraph:
 - $\begin{array}{rcl} Q_{p}(p) & = & p \\ Q_{q}(p) & = & V/2 \\ V_{p}(p) & = & 2p \\ V_{q}(p) & = & V \\ E_{p}(p) & = & 3p \\ E_{q}(p) & = & 3V/2 \\ F_{p}(p) & = & p+2 \\ F_{q}(p) & = & V/2+2 \end{array}$

⁸²⁷ with, as a corollary, the following:

$$\begin{array}{rcl} F_p &\leq & F \\ F_q &= & F \end{array}$$

Hence, a division in the "cyclic case" cannot generate shapes with a larger number of faces than the mother cell. In addition, one of the two daughter cells has systematically the same

shape as the mother cell.

Now it remains to enumerate the number N(p) of different *p*-divisions for a given mother cell shape. The number of 1-divisions is simply:

$$N(1) = V$$

For the 2-divisions, we must distinguish the tetrahedral shape from the other ones because of symmetries of the 2-divisions in this shape:

$$N(2) = \begin{cases} E/2 & \text{if } V = 4\\ E & \text{otherwise} \end{cases}$$

The number of 3-divisions (meaningful only for the two shapes with $V \ge 6$) is the number of pairs of adjacent edges in the mother cell graph. There are three pairs of adjacent edges at each vertex. For the triangular prismatic shape, care must be taken that the two triangular faces induce symmetries. On each face, there are indeed three pairs of edges that define the same division ("cyclic" case). Hence we have

$$N(3) = \begin{cases} 3V - 5 & \text{if } V = 6\\ 3V & \text{if } V = 8 \end{cases}$$

The 4-divisions are meaningful only for the cuboidal shape. They are obtained either by separating opposite quadrilateral faces of the mother cell ("cyclic" case) or by separating one vertex and its three connected neighbors from the other four vertices ("acyclic" case). Taking care of symmetries, we thus have:

$$N(4) = F/2 + V/2$$

= $1 + \frac{3}{4}V$

p/V - p	1/3	2/2
N(p)	4	3
p-shape	4.6.4	6.9.5
q-shape	6.9.5	6.9.5

Table 1: Divisions of the tetrahedral cell shape (4.6.4).

Now we can compute the expected proportions of cell shapes resulting from the division of a given cell shape, under a discrete uniform probability distribution over the space of possible divisions. In the sequel, we refer to each shape by the triplet V.E.F.

The possible outcomes of the division of a tetrahedral (4.6.4) mother cell are given in Table 1. From this table, we obtain that the expected proportions of cell shapes following the division of a 4.6.4 cell are:

Daughters of 4.6.4
$$\begin{cases} P(4.6.4) &= \frac{4}{14} & (28.6\%) \\ P(6.9.5) &= \frac{10}{14} & (71.4\%) \end{cases}$$

The possible outcomes of the division of a triangular prismatic (6.9.5) mother cell are given in Table 2. From this table, we obtain that the expected proportions of cell shapes following the division of a 6.9.5 cell are:

Daughters of 6.9.5
$$\begin{cases} P(4.6.4) &= \frac{6}{56} & (10.7\%) \\ P(6.9.5) &= \frac{11}{56} & (19.6\%) \\ P(8.12.6) &= \frac{39}{56} & (69.9\%) \end{cases}$$

⁸³⁸ The possible outcomes of the division of a cuboidal (8.12.6) mother cell are given in Table 3.

⁸³⁹ From this table, we obtain that the expected proportions of cell shapes following the division of

⁸⁴⁰ a 8.12.6 cell are:

$$\text{Daughters of 8.12.6} \begin{cases} P(4.6.4) &= \frac{8}{90} \quad (8.9\%) \\ P(6.9.5) &= \frac{12}{90} \quad (13.3\%) \\ P(8.12.6) &= \frac{24}{90} \quad (26.7\%) \\ P(10.15.7) &= \frac{46}{90} \quad (51.1\%) \end{cases}$$

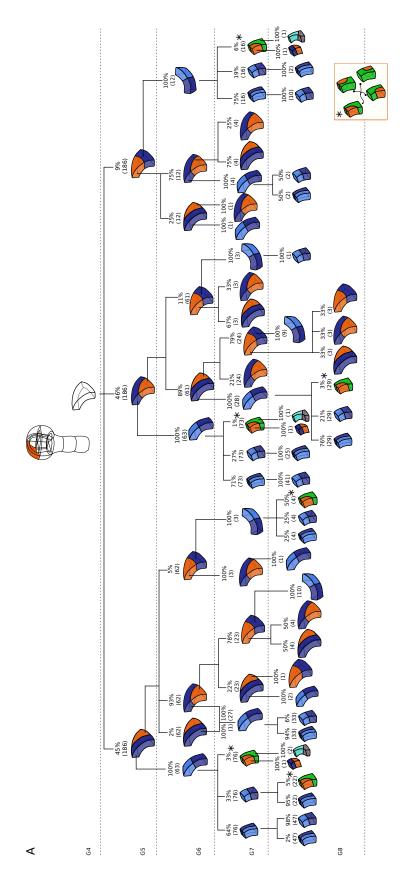

p/V - p	1/5	2/4	$3/3^{lpha}$	$3/3^{eta}$
N(p)	6	9	12	1
p-shape	4.6.4	6.9.5	8.12.6	6.9.5
q-shape	8.12.6	8.12.6	8.12.6	6.9.5

Table 2: Divisions of the triangular prismatic cell shape (6.9.5). α refers to the case where the *p*-subgraph is acyclic, β to the case where it is cyclic.

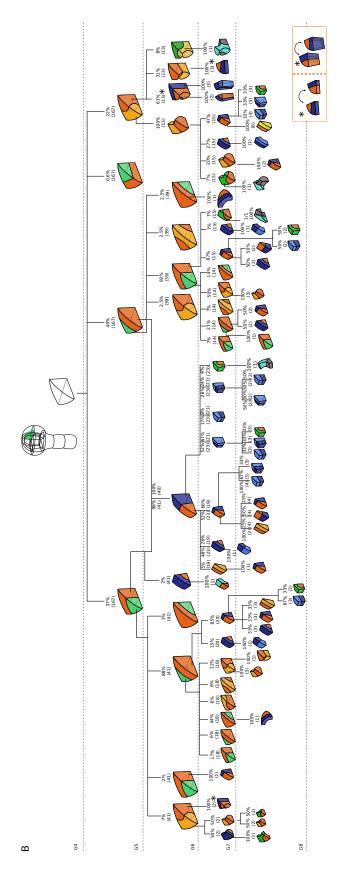

p/V - p	1/7	2/6	3/5	$4/4^{lpha}$	$4/4^{eta}$
N(p)	8	12	18	4	3
p-shape	4.6.4	6.9.5	8.12.6	10.15.7	
q-shape	10.15.7	10.15.7	10.15.7	10.15.7	8.12.6

Table 3: Divisions of the cuboidal cell shape (8.12.6). α refers to the case where the *p*-subgraph is acyclic, β to the case where it is cyclic.
